Competent electrical engineers state that in cases where there is great density of traffic or steep grades or heavy train loads the electrical method is the economical method. The same way of steel will carry more people and goods and it is not good engineering economics to put a 2000-kw power house on wheels. Fortunately there have been tried out several systems of electrification of trunk lines, and it is not a hazy issue, but one definite and worked out. My scheme would be to start a general electrification of our steel highways, give honest labor to honest people, and build up a much-needed permanent public improvement.

The railroads, shipper and people are in this province controlled and dominated by the Interstate Commerce Commission. This judicial administratory board fixes rates and adjusts differences. It has been well argued that this board should set its seal of approval on all emissions of railroad securities.

Should such a plan as I have outlined be proposed and the electrification of our large trunk lines start in a comprehensive and intense manner, and should the Interstate Commerce Commission allow the emissions of securities bearing a high rate of interest and with liberal provisions for amortization and depreciation due to advance in the state of art, and such increase in rates as would justify such an expansion, the good effects would be incalculable and as widespread as a rain from heaven in time of drought, which falls on the just and on the unjust.

The copper mining, smelting, and refining industry would flourish. The business of fabricating copper and the electrical industry would revive. The steel and iron trade would be helped. Our energy that might go to waste would be put in useful permanent form.

If such securities ware made safe investments by care and intelligence, and if some of them were so strong that they were legal for savings banks, the money would flow in an endless chain, provided such people as were benefited kept their mental equilibrium.

The collateral problem of our country is to prevent waste not so much by stern necessity as by wisdom and thrift. If we can hold together in spirit, we can emerge from the crisis far stronger than we entered it. High rates of interest will draw out capital from its hiding and keep gold in the United States. Just now the banks are borrowing money at 3 per cent from the Government and loaning it to the people at from 8 per cent to 10 per cent. Good business indeed both for people and the banks, provided the banks put credit in safe hands and the people can earn enough with the capital to pay the increased rates.

This national electrification of railroads must be conditioned on high rates of return. This limitation is in line with the theory propounded and exposited in *Metallurgical and Chemical Engineering* that applied science has opened up as it were a new virgin country where profits are large and usufruct of capital and intelligence is great.

The scheme that I propose is not a chimerical one, at least its benefits would not be ephemeral. Of course, I know that I have elaborated it and elucidated it in the roughest sort of pencil sketch. But put on the drafting board in clear and precise form, it would be a magnificent plan of commercial engineering.

WOOLSEY MCA. JOHNSON.

Hartford, Conn.

### Cost Accounting and the Work of Accountants

*To the Editor of Metallurgical & Chemical Engineering:*

SIR:—In reply to Mr. Ernest G. Ashby's discussion of my article on metallurgical cost keeping, I believe that in the main we agree except as to the title of the employee who calculates the cost data.

It might be inferred from my article that this should fall on the engineer. This is not my intention. There should be someone whose duties are to keep cost data available to the executive, to enable him to deal in detail with his problem. This man should preferably be both an accountant and an engineer. This is usually impossible. If he is an accountant, he should give such cost data as may be prescribed by the engineer, superintendent, etc., and not by the auditor or office force.

The vital point of the entire matter, to my mind, lies in the unit system. Then the particular unit used becomes paramount. Not many systems carry milling costs on any unit basis, except the per ton basis. This unit is based on the number of tons milled. For example: A mill handles 500 tons of ore through the stamps in twenty-four hours. Say 400 tons of this is then slimed in the tube-mills. Is the cost of tube-milling calculated as it should be on the 400-ton basis, or is it wrongly calculated on a 500-ton basis?

The foundation of efficiency is the largest accomplishment for the least expenditure. The words "largest" and "least" are the superlative degrees of comparison. Therefore, costs must be expressed in units capable of comparison to be of any value to the executive. For instance: In the 1913 report of the Alaska Treadwell Gold Mining Company it is stated that pumping costs 10 cents per ton of ore milled. From this simple statement, can anyone state whether that pumping was efficiently done or not? From a cost analysis point of view this should be stated in gallons-feet. To say that pumping costs 10 cents per ton of ore milled is meaningless and worthless and in itself gives the engineer or superintendent no idea of the efficiency of the work.

I admit that the above figure is sufficient for the stockholder, but it does not indicate the efficiency of the pumps to the superintendent.

Naturally these results can be dug out of any system of bookkeeping, but it is my experience that when this is necessary they are never dug. These facts should not only be readily obtainable, but they should show on the regular reports so that any sudden change manifests itself at once.

As usual, an accountant cannot accept any set of figures that do not check to the cent. I still maintain that cost keeping contains errors in spite of the most rigid system, but as long as they allow comparisons, the errors are negligible.

In considering costs, as stated above, comparisons are the vital point of all systems. Halbert T. Gillette in his "Hand Book of Cost Data" goes as far as to say:

"Since cost keeping has as its primary object the reduction of costs, since comparison of results secured by different men or different machines or different methods are necessary, it follows that standard wages and standard prices of materials must be used. It may happen that on one job the cement may be purchased at different times at prices ranging from $1.20 to $1.50 per barrel, and that common laborers may receive from $1.50 to $1.75 a day. In comparing unit costs a standard price of cement should be assumed as $1.30 per barrel and a common labor standard wage as $1.50 per day. Then comparisons become possible. A bookkeeper cannot assume any rate of wage or any price; he must give the actual wage or price. A cost keeper usually finds it desirable to use standard wages or prices which approximate the average, or actually are the average."

The cards shown in my article are merely one form for obtaining this data on a unit basis. Even more than unit measurements are necessary, according to Gillette:

"Cost keeping records should state conditions, such as weather, distance of haul, etc., which are essential to interpretation of results. Sketches showing design of structure should form part of permanent cost records. Such things are entirely foreign to bookkeeping, and if placed upon bookkeeping records simply serve to confuse them."

I agree with Mr. Ashby that the accounting and engineering departments must work together, but I object to the accounting department determining what cost data the engineering department shall use. This may not be so in Mr. Ashby's case, but I am certainly warranted in saying that in most cases the engineering department must accept the cost data as given to them.

JUSTIN H. HAYNES.

Denver, Colo.

## Nevada State Mine Rescue and First Aid Meet

*To the Editor of Metallurgical & Chemical Engineering:*

SIR.—The Nevada State Mine Rescue and First Aid Contest, held on the Mackay Athletic Field of the University of Nevada at Reno, Nevada, on Labor Day, September 7, 1914, was of particular interest in several respects. It was the first strictly metal mine meet to be held in the United States, and the first mine rescue meet to employ a mine rescue maneuver.

Prior to this meet, car No. 5 of the United States Bureau of Mines had been touring the State of Nevada, and the miners who paticipated had been trained by Mr. E. Steidle, mining engineer, and Mr. George W. Riggs, first-aid instructor, both attached to this car. They trained sixty-nine miners and ten students of the University of Nevada in mine-rescue work, and one hundred and thirty miners and fiteen students in mine first-aid work. In addition to this, Mr. Steidle gave week-end lectures on mine rescue and first aid, reaching in all some forty-four hundred miners.

The distribution of the men, who were trained in the work, is shown in the following table:

| Mining Districts | Men Trained in Mine Rescue Work | Men Trained in Mine First Aid | Number of Oxygen Breathing Machines |
|---|---|---|---|
| Ely | 10 | 40 | 6 |
| Virginia City | 10 | 10 | 7 |
| Goldfield | 10 | 10 | 6 |
| Tonopah | 24 | 30 | 13 |
| Round Mountain | 5 | 10 | 2 |
| Blair | 0 | 10 | 0 |
| Wonder | 5 | 10 | 2 |
| Fairview | 5 | 10 | 2 |
| University of Nevada | 10 | 15 | 1 |
| Total | 79 | 145 | 41 |

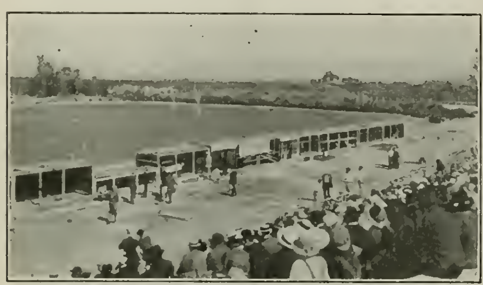
The contest held at Reno was under the auspices of the Engineering College of the University of Nevada, with the co-operation of the U. S. Bureau of Mines, the American Red Cross Society and the Nevada Industrial Safety Association.

In the mine rescue problem a model drift, constructed of timber, lathes and tarred paper, after a design by Mr. Steidle, was employed. This drift was open on the side toward the grand stand, with the exception of one section, which was closed by means of windows, and in which dangerous gases were confined. The drift was 6 in. in height and 260 in. in length and was made up of the following sections: 80 in. of open drift, 20 in. of drift in which a hanging fall was supposed to have taken place and which was, therefore, only 3 in. in height; 20 in. more of open drift, a 40-in. gas and smoke chamber with an inclined obstacle in the center, 20 in. of open drift, 20 in. in which a fall was supposed to have taken place and in which an opening 3 in. high was left above the fall, and finally 60 in. of open drift to the face.

The participants were examined by doctors and then tested and adjusted their apparatus and stood a three-minute trial in a small test-house filled with gas and smoke. Then each team in turn entered the model drift to rescue a miner, supposed to be overcome near the face. Stretcher and breathing apparatus were carried for the use of the injured miner, and a life line was used, and all precautions were taken as suggested by the U. S. Bureau of Mines.

The first prize was won by the Tonopah Mining Company's team. The three other competing teams were from the Veteran Mine of the Nevada Consolidated Copper Company; the Tonopah Belmont Development Company, and the Goldfield Consolidated Mines Company.

Eight teams took part in the Miner's First Aid Contest. The problem in this contest was to aid a miner found in a drift, under a fall of rock, in contact with electric wire, unconscious and suffering from numerous injuries. The first prize was won by the McGill Concentrator team of the Nevada Consolidated Copper Company. The other contestants were the Tonopah Extension Mining Company, the Tonopah Belmont Development Company, the West End Consolidated Mining Company, the Goldfield Consolidated Mines Company, the Tonopah Mining Company and the Veteran Mines of the Nevada Consolidated Copper Company. Three teams of University students contested among themselves.



NEVADA STATE MINE RESCUE AND FIRST-AID MEET

The first prizes were a silver shield and a silver loving cup, presented by the Nevada Industrial Safety Association to the winning teams, while the American Mine Safety Association presented medals to the individual members of these teams. The other prizes distributed in these contests included subscriptions to *Metallurgical & Chemical Engineering* and other technical papers contributed by the publishers, and miners' lamps donated by manufacturers.

Mackay School of Mines,
University of Nevada.

## The Non-Ferrous Metal Market

For sixty days the domestic market for non-ferrous metals has been subject to serious disturbance with wide fluctuations in prices. Curiously enough, different metals have been variously affected, to advantage in some cases and unfavorable in others.

**Copper.**—There has been no wholesale market for this metal for some weeks, and no quotations are available. American producers have acted as a unit in curtailing production about one-half, which will practically compensate the loss of the foreign market, and it is expected that the market will be in good shape when business can be resumed on a normal scale.

**Tin.**—Quotations in this market are still nominal, and with an increasing supply have tended to fall off. The fancy prices asked during August have disappeared, and late quotations are about 33 cents, New York.

**Lead.**—This market has remained weak, and the price of 3.90 cents, New York, has been maintained by the A. S. & R. Co.

**Spelter.**—Prices for this metal have receded from the high figures quoted shortly after the war began. Demand has now become slack. A high price of 6.10 cents was reached on August 26, since which time a steady decline has occurred. Latest quotations are about 5.50@5.65 cents, St. Louis, and 5.65@5.70, New York.

**Other Metals.**—Prices for antimony have risen to from 10½ to 12½ cents for various brands. Aluminium is quiet at 20@20½ cents, New York. Quicksilver showed a stiff advance in price, and is quoted at $75@$85 per flask of 75 lb., New York, about double the prices before the war.

## The Western Metallurgical Field

### Smelter-Fume Damage in Salt Lake Valley

Study of the smelter-fume problem and the effect of smelter gases on agricultural crops is being conducted by the companies operating in the vicinity of Salt Lake City, Utah. The result to date is that two of the plants, those of the United States Smelting Co., at Midvale, and the American Smelting & Refining Co., at Murray, are fumeless as far as the discharge of visible gas is concerned. In fact, to a stranger the plants have the appearance of being closed and not in operation. The Garfield Smelting Works, however, situated at the north point of the Oquirrh range, west of Salt Lake City, continues to discharge into the atmosphere the gases from the smelting and roasting furnaces. The same is true of the Tooele plant of the International Smelting & Refining Co., situated southwest of Salt Lake City, on the western side of the Oquirrh mountains.

Both the Midvale and Murray smelters use the Sprague process for neutralizing the sulphuric acid in the gases, and the products are collected in bag houses. This still leaves sulphur dioxide unaffected, and this gas is discharged into the air. Under normal weather conditions the ill effect of smelter fume in the valley has been greatly minimized due to these improvements, but this year the damage has been increased, due to an unusual snow storm which occurred in June. The average quantity of sulphur dioxide in the valley atmosphere south of Salt Lake City is about 0.25 part per million. The highest is one part per million, and this is observed when northwesterly winds blow fumes from the Garfield smelter over the valley. The lowest quantity observed is a trace, and this condition exists when northerly winds clear the valley of fumes. In spite of the improvement in conditions, however, and the effort of the smelters to meet the imposed requirements, there is more or less friction with the farmers, and damage suits aggregating hundreds of thousands of dollars are pending against the smelters. The Murray plant is said to be working under an agreement with the farmers for compensation for damage, and the Midvale smelter is reported to be seeking a legal modification of restrictions whereby it can smelt an increased daily tonnage of sulphide ores.

Some interesting experimental work is being done by the American Smelting & Refining Co., which has purchased a farm three miles north of the Murray plant. This farm comprises 50 acres of ground, and was one of the poorest farms in the valley. It is not only in the zone of possible fume damage, but it contains an undrained area and some alkali spots, and is therefore suited to the study of a variety of causes of poor crops. On this farm the smelting company has erected a laboratory where a corps of experts conduct their studies. Field tests of the effect of different percentages of sulphur dioxide on various growing crops are made, and the results recorded for future use. Studies are also made of the diseases of local crops and of the various insects which affect the yield. These pathological studies already have resulted in the discovery of bacterial and fungus diseases, the effects of which the farmer has attributed to smelter fume.

The attitude of the American smelting company to the farmer is one that should improve relations between the two interests. The experimental farm is being conducted not only in the interest of the smelter, but it serves also as a demonstration farm for the local farmers. The latter are encouraged to visit the farm, and are given instruction by the experts on methods of improving their farm work. They are shown also the effect of various diseases on crops and are taught how to eradicate the troubles which are not due to smelter smoke. Instead of antagonizing the farmers and claiming that no damage is done, the smelter is apparently admitting evident damage, at the same time protecting itself against imposition. It is an odd fact that farmers in the zone of actual damage are most reasonable and easiest to deal with, while those who are outside the zone of damage cause a great deal of trouble. The work of the American Smelting & Refining Co. should go a long way toward creating a better spirit between the contending factions, as well as determining in a scientific way the actual damage of sulphur dioxide, and gaining a basis for settlement of damage claims.

### The War and the Metallurgical Industry

The state of uncertainty which prevailed in the mining and metallurgical industries immediately following the declaration of war in Europe has largely been replaced by a spirit of optimism and assurance that accompanied a calm study of the situation. With the exception of the curtailment in copper production, there have been no serious disturbances in the metal producing centers of the West. The slump in silver was but temporary and due only to the fact that smelters did not know where they were to dispose of their stocks; hence they could not assure the miner a normal price for his silver ore. The Cobalt district in Canada was vitally concerned, but even there the bullion shipments have resumed their normal proportions, and many companies have resumed operations after a short period of non-production.

Up to the present the lead market has not shown the activity or rise in price anticipated by many operators. Nevertheless, according to well informed smelting officials, it is almost certain that lead will show an advance in the near future. In fact, the head of one of the largest smelting concerns is quoted in the public press as saying that the United States is on the eve of a great opportunity in all commercial lines, and has a chance to supply the world with needed metals. Metal manufacturing industries are suggested as a logical development in order to take care of our excess metal production.

As anticipated, the spelter market has enjoyed a prosperous turn. A stimulus has been given to zinc mining, milling and smelting, and such centers as Joplin have experienced a revival of interest such as has not been known for years. Old properties have been reopened; old mills put in commission; dumps leased for operation, and prospecting stimulated.

The United States Geological Survey has shown commendable activity in issuing so promptly various bulletins on our mining and metallurgical industries. One of the most important is *Bulletin* 599, "Our Mineral Reserves—How to Make America Industrially Independent." It contains an inventory of our mineral resources, and gives some details on fuels, metals and non-metallic minerals of commercial importance. In addition to this, numerous press bulletins have been issued giving authoritative comment on the status of the metals.

From the chemical point of view, the situation in the West is most concerned with the supply of cyanide, and the possibility of domestic production supplying the demand. Such as are interested in the prospect of making cyanide we refer to back files of this journal, in which will be found many technical articles dealing with this industry. Particularly in our issues for March and April of the current volume will be found articles on the manufacture of cyanide and cyanamide, the latter product being of immediate interest as a possible source of the former.

Western metallurgical works, as well as custom chemists and assayers, have suddenly found that their dependence on European manufacturers is greater than they had hitherto thought, particularly for chemicals and filter papers. Prices of these articles have increased several fold and the supply is at present limited. Among other articles affected by the war are graphite, barytes, manganese, tin, arsenic, antimony, radium, potash, zinc dust and flint pebbles. In the case of some of these and other materials, we have been dependent on Europe for supplies in quality as well as quantity, and the present situation emphasizes the importance of developing as far as possible our own resources along these lines. Time will be required to get new industries started, and even then our manufacturers must give consideration to the possibility of maintaining their markets after conditions in Europe return to normal.

Among the large copper companies, Utah Copper Co. will pay the usual dividend for the quarter ending with September. Chino has reduced the rate from 75 cents to 50 cents for the current quarter, and Ray Consolidated and Nevada Consolidated have passed the dividends.

### Pneumatic Flotation Process

New methods of accomplishing ore flotation are being rapidly developed, and a wide variety of means used to accomplish the purpose. One of the most interesting as well as successful methods is that of using air as the agitating and froth-producing medium. Plants using this method have been installed by the General Engineering Co., of Salt Lake City, Utah, at the National mill, in Idaho, the Magma, Miami and Inspiration in Arizona. The ore is mixed with oil and water and fed into a separator which consists of a rectangular cell having an inclined false bottom covered with fabric. Compressed air admitted into compartments below the false bottom passes upward through the fabric and is divided into innumerable small bubbles which form a froth 12 to 18 inches deep in the cell. Mineral concentrate rises with this froth and overflows the sides of the cell, while gangue flows down the inclined bottom and is discharged. If desired, the first cell can be used as a rough concentrator, and the valuable product re-treated in another cell. The products from several roughers could be combined on one cleaner. Pine oil has been found to be a good floating medium, and is used in the oil mixture in varying proportions.

### Camp Bird and Santa Gertrudis

These two English companies controlling the Camp Bird mine in Colorado and the Santa Gertrudis in Pachuca, Mexico, have become suddenly involved in financial loss due to the collapse of commercial enterprises in which the former chairman of the companies, Mr. A. M. Grenfell, was interested, and in which funds of the mining companies were invested or on deposit. In an official statement issued by Mr. H. C. Hoover, who has accepted temporarily the chairmanship of both companies, it is announced that the probable total loss will not be as great as at first anticipated. Camp Bird probably will sustain a loss of $50,000, and Santa Gertrudis $135,000. Both companies, however, are sound mining and metallurgical enterprises, and will not be seriously crippled by these losses. The Santa Gertrudis mill has been closed owing to disturbances in Mexico, but the Camp Bird is in operation.

### Butte & Superior

It is reported that July operations at this property in Montana showed an improvement in milling results. The former recovery of 90% was maintained and at the same time the grade of zinc concentrate was raised from 51.73% in the first quarter to 55% early in July. These concentrates are sold on a 50% zinc basis, and any improvement over that grade brings a premium, just as a deficiency entails a penalty. The property is now operating under normal conditions, producing and treating about 1000 tons of ore per day.

### Model Town at Anaconda

It is reported that the Anaconda Copper Mining Company, through its subsidiary, the Deer Lodge Valley Farms Company, is to establish a model town for the employees of the smelter at Anaconda. The new settlement will be known as Opportunity. It is located east of Anaconda in the Deer Lodge Valley, where a large acreage has been divided into five and ten acre tracts on which the smeltermen may establish a home and garden plot. The Anaconda trolley system will be extended to the new town, and the Anaconda company will assist the new settlers in every way to establish themselves in comfortable homes. The scheme includes the establishment of legitimate forms of amusement for adults and children, but saloons are barred.

## The Iron and Steel Market

The great uncertainties attending any attempt to forecast even roughly the effects of the European war, as referred to in our report a month ago, have been only slightly reduced by the progress of time. It was impossible to judge of the prospects by precedents, for of precedents there were absolutely none. For judgment at the present time we have nothing but the concrete experience of two months and that is very far from conclusive.

The buying power of the so-called neutral or consuming countries has been vastly reduced. Financing of new projects has practically ceased, and funds are usually lacking even for making purchases for current and everyday consumption. When funds are available it is difficult to purchase exchange or to establish London or New York credit. Despite the fact that Germany, France and Belgium are physically unable to export any considerable quantity of iron and steel, and Great Britain's manufacturing resources are somewhat curtailed, the demand from neutral markets is curtailed so much more that Great Britain is unable to sell all the goods she can produce. To the United States there has come little inquiry from neutral markets, and the small iron and steel export trade the United States was conducting just before the war, amounting to about 140,000 tons a month, has not been fully restored, and may not be for several months.

The early idea that the chief desideratum for an iron and steel export trade was ocean-carrying facilities, was quite promptly exploded. Exports to Canada, which move entirely by rail, have been greatly reduced. The fact that war has throttled buying capacity, rather than shut off supplies, is indeed proved by the remarkable case of the United States itself. As indicated in the review a month ago, a first effect of the war was to encourage buying in a few quarters, by fear of possible scarcity later, but even at the outset this tendency was slight. The more important trend then mentioned, as to a stoppage of new projects requiring financing, is now being felt in full force, and even purchases for ordinary current requirements are greatly reduced. The total volume of buying in the United States is considerably diminished.

Steel mill operations are necessarily decreasing, but the decrease lags behind the decrease in buying through, there having been on order books a moderate accumulation of business. While the steel mills operated at nearly 70 per cent. of capacity in July, at the close of September they are operating at not more than 50 per cent and all the prospects are that the rate will diminish further, and probably to the smallest percentage of capacity that has ever obtained in the history of the American steel trade.

The more distant future of the American steel industry cannot be the subject even of intelligent guessing. An illustration of the wide uncertainties may be of interest. Through the refinements of modern practice the amount of coal involved in the production of a ton of finished steel has been very greatly reduced and by reason of this the iron and steel developments in the great Minette ore district have been rapid in recent years. These developments have been on both the German and the French side, but when the war is over there is every reason to believe that practically the whole district will be either German or French. If German, that country will probably include Belgium also, and Germany would then be a close second to the United States in iron and steel production instead of a relatively distant second. If the territory falls to France, that country will rank second and Germany third, while England, with no change within her borders, will drop from third to fourth place.

The producing section which would be transferred from the German colors to the French has found its market chiefly in Germany, but would then have to find a new market. There is no reason to suppose that France would experience much increase in domestic consumption, and that country would therefore probably become in time a keen competitor in the export trade. In circumstances of which this illustration is one suggestion, it seems quite impossible to make guesses as to what place the American iron trade will occupy in the world's commerce after the war, while it does seem reasonable to conclude that during the war no spectacular demand for iron and steel can arise in any part of the world.

### Pig Iron

The pig iron market has been stagnant. Buyers have been extremely conservative and purchases have been few. Actual consumption has decreased and shipments of merchant furnaces have been curtailed. As the producers must necessarily be conservative there has been a decrease in production, and the merchant furnace output of pig iron is the smallest for a long time, with prospects of further reduction. The price situation having already been well liquidated there have been no material declines. The eastern market has advanced a trifle and the Chicago market has lost a little ground.

Current quotations are partly nominal: No. 2 foundry, f.o.b. Birmingham, $10 to $10.25; delivered Philadelphia, $14.70 to $14.95; f.o.b. furnace, Buffalo, $13 to $13.50; f.o.b. furnace, Chicago, $13.25 to $13.50; at valley furnaces (90 cents higher delivered Pittsburgh), Bessemer, $14; basic, $13; No. 2 foundry and malleable, $13 to $13.25; gray forge, $12.50 to $12.75. Ferromanganese has weakened after the early excitement, and prompt shipments from American stocks are quoted at about $85, shipments from England in limited quantities being quoted at $80, f.o.b. Baltimore.

### Steel

The large mills advanced their quotations on billets and sheet bars early in September, and have since been quoting $21 and $22 respectively. Small lots are occasionally offered by the smaller mills at somewhat lower figures, while deliveries on current contracts are also at a much lower level. In the minds of buyers at least there is serious question whether the present quoted prices will ever be the subject of extensive trading. Rods are about $26, Pittsburgh. A few sales have been made for export to England at a slightly higher level, while domestic contracts now being filled average less than $25.

### Finished Steel

There have been scarcely any changes in quoted prices on finished material.

The quoted prices are not being seriously tested, as new buying is practically at a standstill, and specifications on old contracts, made before the recent advances, are materially reduced.

Prices named below are regarded as representing the market, such as it is, and f.o.b. Pittsburgh unless otherwise stated.

Rails, standard sections, 1.25c. for Bessemer, 1.34c. for open-hearth, f.o.b. mill, except Colorado.

Plates, tank quality, 1.20c.

Shapes, 1.20c.

Steel bars and bands, 1.20c., base; steel hoops, 1.30c., base.

Iron bars, 1.25c., Pittsburgh; 1.17½c., Philadelphia; 1.07½c., Chicago.

Sheets, blue annealed, 10 gage, 1.45c.; black, 28 gage, 2.00c.; galvanized, 28 gage, 3.00c.; painted corrugated, 28 gage, 2.20c.; galvanized corrugated, 28 gage, 3.05c.

Steel pipe, ¾ in. to 3 in., 80 per cent off list.

Steel boiler tubes, 3½ in. to 4½ in., 72 per cent off list.

Wire nails, $1.60, base; smooth fence wire, 1.40c., base; galvanized fence wire, 1.80c., base; galvanized barb wire, 2.00c.

Standard railroad spikes, 1.45c., Pittsburgh; 1.50c., Chicago.

Structural rivets, 1.55c.; boiler rivets, 1.65c.

Cold rolled shafting, 66 per cent off list.

Chain, ⅜ in. proof coil, 3.05c.

---

**An alloy for welding copper and nickel**, patented in this country by Canzler and Samesreuther (1,103,482) consists of copper, phosphorus and a small percentage of silver.

**Light, strong castings**, adapted for use where high temperatures are employed, can be made of 85 to 87 per cent aluminium, 9 to 11 per cent zinc, 2 to 4 per cent lead and 1 to 3 per cent of a strengthening element such as copper or nickel. The formula is patented by C. P. Van Gundy (1,098,137). Tellurium is suggested as a strengthening element in aluminium alloys, in patent (1,102,618) granted to Samuel Wein.

**Deposits of phosphate** near the Red Sea have been largely developed in the last two years, according to the Egyptian *Gazette*. The mines are worked by a British company, and the product is exported. The rock contains 65 per cent or more of tri-calcium phosphate. Other Egyptian deposits also are being exploited under concessions. The total output of phosphate rock in 1913 was a little over 100,000 tons, almost all of which came from the Red Sea deposits. Shipments are made mainly to Japan. The local demand for raw phosphate is almost negligible, and superphosphate is imported. Projects are being considered, however, for the local manufacture of superphosphate.

## Program of Niagara Falls Meeting of the American Electrochemical Society

The twenty-sixth meeting of the American Electrochemical Society will be held in Niagara Falls from Oct. 1 to 3, with hotel headquarters at the Clifton Hotel.

*Thursday, Oct.* 1.

9:30 a. m. Reading and discussion of papers at the Clifton Hotel.

The Constancy of Base-Metal Thermocouples as Affected by Their Microstructures: O. L. Kowalke.

The Evaporator and the Power Problem in Electrochemical Plants: Otto Mantius.

On Electrometric Titrations: Henry Ziegel.

The Reproducibility of the Copper Electrode: Frederick H. Getman.

The Source of Impurities in Cathode Copper: Lawrence Addicks.

The Electrolytic Determination of Nickel: N. Judson Marsh.

Experiments on the Quantitative Determination of Radium: Herman Schlundt.

2 p. m. Excursion to Foster's Flats.

8:30. Smoker in Clifton Hotel.

*Friday, Oct.* 2.

9 a. m. Excursion to plants on the American side. Among those to be visited will be the power houses, the Acheson Graphite Company (who will show some features not hitherto exhibited), the Niagara Alkali Company (under usual reciprocal restrictions), Spirella Corset Company (triple-plating department), etc.

2 p. m. Reading and discussion of papers at the Clifton Hotel.

Silicidized Carbon: Silfrax: F. J. Tone.

The Electrolytic Insulation of Aluminum Wire: C. E. Skinner and L. W. Chubb.

Electro-Percussive Welding: C. E. Skinner and L. W. Chubb.

On the Formation of a Badly Conducting Film on a Copper Anode in Copper Cyanide Solution: W. Lash Miller.

Tin Salts of Mineral Acids: F. C. Mathers and B. W. Cockrum.

Electrodeposition of Lead from Lead Lactate and Lead Formate Solutions: F. C. Mathers and B. W. Cockrum.

Electrodeposition of Lead from Lead Acetate Solutions: F. C. Mathers.

7 p. m. Dinner at Clifton Hotel, to be followed by an illustrated lecture: "The Physical Nature of Color," by C. E. Kenneth Mees (director of Research Laboratory, Eastman Kodak Company).

*Saturday, Oct.* 3.

9:30 a. m. Symposium on "The Practical Side of Electrochemical Investigation," at the FitzGerald Laboratories (Highland and Whirlpool Avenues, Niagara Falls, N. Y.). This symposium will consist of a number of informal demonstrations of apparatus, methods, and materials used in electrochemical investigations, or as electrochemical aids to chemical investigations. The symposium will proceed throughout the day, with an intermission at 1 p. m., when a complimentary luncheon will be tendered by the Niagara Falls members at the Cliff Distributing Company's substation, Highland and Whirlpool Avenues.

In the evening there will be an informal rendezvous at the Niagara Club.

The privileges of the Niagara Falls Country Club will be extended to members throughout the meeting.

Mr. F. A. Lidbury, works manager of the Lidbury Electrochemical Company, is the president of the American Electrochemical Society

## The Effect of Steam Upon Magnesite Brick or Calcined Magnesite

BY R. H. YOUNGMAN

Carbonate of magnesia or magnesite is found chiefly in Greece, Austria-Hungary, Africa, India, and in California in the United States. The deposits of Greece and California are of the white massive character and as a rule of very pure quality. They are not as suitable for refractory purposes in metallurgical processes as the Austro-Hungarian magnesite, on account of composition and high cost of preparation. The white magnesites are used principally in caustic form as flooring cement and for the manufacture of carbonic acid gas, the carbonate as mined containing approximately 50 per cent of $CO_2$ (carbonic acid gas) which may be driven off for this purpose at comparatively low temperature. A few refractory brick are made from white magnesite, but difficulties of manufacture and high cost render the demand very slight.

It is with the Austro-Hungarian magnesite that the users of magnesite in this country are most concerned. The material occurs in a crystalline formation and is gray in color with tinges of brown. In comparison with the white magnesite it differs in composition and formation. The chemical composition is the most important difference. Comparative analyses of the two kinds of magnesite, calcined, are as follows:

| | Austro-Hungarian | White |
|---|---|---|
| Silica ($SiO_2$) | 2.75 | 2.50 |
| Alumina ($Al_2O_3$) | 0.50 | 0.25 |
| Iron oxide ($Fe_2O_3$) | 7.00 | 1.00 |
| Lime (CaO) | 2.50 | 2.25 |
| Magnesia (MgO) | 87.00 | 93.00 |
| Loss on ignition | 0.75 | 1.00 |

The impurities in the Austro-Hungarian render it less refractory, and it will frit more readily at operating temperatures, which is a very important property, especially in open-hearth practice in building the bottom and repairing the slag line. In the calcined form, for commercial uses, Austro-Hungarian magnesite has a rich brown color and white magnesite is either white or a very light brown, depending upon the thoroughness of calcination.

The chief uses of magnesite brick are in open-hearth steel furnaces, copper converters, reverberatories and settlers, and electric furnaces. Their use is spreading considerably where strong basic slags, mill cinder and strongly metallic slags are encountered, such as the bottoms of forging, heating, and welding furnaces.

It is an interesting fact, and one of importance to all users of magnesite, that when subjected to the action of steam, magnesite in calcined form, or even the most thoroughly burned brick, will hydrate, similarly to the action of calcined lime when water is added. This hydration takes place to equal degree in all brands of magnesite brick made in the United States or Europe. The effect of the hydration is disintegration to an almost impalpable powder. It does not seem to bear any relation to the content of lime or other impurities, as the tests showed the same results for Austro-Hungarian as for white or very pure Grecian magnesite.

Tests were conducted by placing brick in a steam-tight cylinder and subjecting it to steam at 100 lb. pressure for a period of two hours, all brick tested showing hydration to the same degree, though it is reasonable to conclude that the action would be somewhat retarded under lower pressure or less severe conditions.

Difficulties of this nature have been experienced in open-hearth furnace bottoms by laying the brick and magnesite bottom over a bed of refractory materials mixed with water. Upon heating up steam is formed and the bottom may be very badly damaged by hydration of magnesite.

This fact, which has not been well established until recently, no doubt accounts for a number of similar troubles which have occurred in years past. It also explains cases of disintegration of burned magnesite brick which have been in contact with steam leaking from coils or steam-heated floors used in manufacturing magnesite brick. It should be made a matter of common knowledge, therefore, so that users of magnesite will be able to guard against trouble of this kind, especially during the initial heating period.

## The Determination of Phosphorus in Scheelite Concentrates

BY E. W. HAGMAIER

The two most common methods for analyzing scheelite concentrates are:

Place 1 gram of the concentrate in a porcelain evaporating dish or casserole and add 75 cc of concentrated hydrochloric acid, and from time to time add potassium chlorate until the tungsten is all oxidized. This will require from 3 to 4 grams. If one does not want to use hydrochloric acid and chlorate, then aqua regia may be used, and the sample is taken to dryness. Take up with dilute hydrochloric acid (½), warm and loosen as much of the tungstic acid from the sides as is possible. Add 15-20 cc of cinchonine solution, some paper pulp, and let stand about half an hour before filtering. Filter and wash with dilute hydrochloric acid to which some cinchonine has been added.

The residue which is tungstic acid, silica, and some iron is burned in a platinum crucible, and then treated with a few drops of sulphuric acid and several cc of hydrofluoric acid and the silica volatilized. The excess sulphuric acid is driven off and the crucible weighed. A sodium carbonate fusion of the residue is then made and the melt is leached out of the crucible with water, and boiled. The tungsten is in solution as sodium tungstate and the iron which was held by the tungsten is precipitated as carbonate. This is filtered and washed with hot water, and burned in the original crucible, this weight deducted from the former weight gives $WO_3$.

In order to determine the phosphorus in these concentrates it is necessary to treat another sample as above, but omit the addition of cinchonine before filtering and in washing. The writer's experience has been that some of the tungsten washes through, necessitating a second filtration after the filtrate has been concentrated. This takes considerable time as the filtrate must again be evaporated to a low bulk after the second evaporation before the phosphorus is precipitated.

It occurred to me that the phosphorus could be precipitated from the cinchonine filtrate by using cerium chloride as a precipitant for the phosphorus.

To the cinchonine filtrate from the scheelite add 10 cc of cerium chloride solution (1 gram cerium chloride, 25 cc hydrochloric acid, 250 cc water), make the filtrate neutral with ammonium hydroxide, boil five or ten minutes, and filter, washing with hot water. Dissolve the precipitate off the paper with hot (1-1) nitric acid and precipitate the phosphorus with molybdate.

The following results were obtained on synthetic mixes with WO 65-70 per cent, $Fe_2O_3$ 4-5 per cent and phosphorus 0.100, 0.150, 0.300, 0.200.

| Phosphorus found | No. 1 | No. 2 | No. 3 | No. 4 |
|---|---|---|---|---|
| | 0.083 | 0.152 | 0.296 | 0.195 |
| | 0.087 | 0.144 | 0.293 | 0.195 |
| | 0.094 | 0.147 | 0.303 | 0.193 |
| | 0.096 | 0.147 | 0.298 | 0.203 |

# Grinding Ore for Cyanidation: A Suggested Modification for All-Sliming Practice

BY W. J. PENTLAND

The following comments are intended to apply to "all-sliming" practice of crushing, and principally to the silver ores of Mexico that call for more extended treatment than do the ordinary docile gold ores of the United States.

It is common custom that the treatment of ore is controlled by what is found necessary for the satisfactory treatment of the most refractory part, even though a large part may not call for that treatment with its consequent cost.

When we follow the incoming ore through the mill, sampling and testing at each successive step, we find that a part separates easily and quickly, gives up its valuable metal with less time of contact and agitation, and often with weak solution. We find that the remaining part also separates easily and quickly, but is of denser and more compact nature, needs longer time of contact and agitation, and also needs grinding and regrinding.

This separation takes place in the classifiers that follow the primary grinders—stamps, chilean mills, or whatever type the primary grinder may be.

### Different Character of Sand and Slime

The first part—the overflow from the classifier—we may call "slime." It is usually the softer and more friable part of the ore; was not made by any effect of the crushing, but was simply released; and contains but very little material that could be considered as having been made in the crushing operation. It constitutes anywhere from 30 to 60 per cent, by weight, of the total ore crushed.

The second part—the discharge from the classifier—we may call "sand." It is usually the harder and tougher part of the ore; is made up of all sizes of particles, from the finest to the coarsest that have passed through the screen; needs regrinding to bring it somewhere near the size of slime to release its valuable content; and requires longer agitation to extract the metal. It constitutes anywhere from 70 down to 40 per cent, by weight, of the total ore crushed. But even if it constitutes only 40 per cent of the total ore, the 100 per cent of the ore will be subjected to the treatment determined as necessary for this 40 per cent. Area of tanks and buildings, stronger cyanide solution, power for agitation, repairs and renewals, all have been provided and are being used on the maximum treatment basis for the total ore, when but a half or less of it requires anything like such treatment.

### Special Treatment for Refractory Part of Ore

It may be argued that it would be another complication to make a separation of these two parts of the ore; but that argument would not apply, for the separation *is always made*. It is made at the classifiers; and moreover, one of the parts is always thickened for the immediately following regrinding, in fact is too thick for agitation. This is the "sand" part. It does not matter that this part may be subsequently ground to the same size as the slime; it is still sand in everything but size; it is dense and compact; and even though it may not call for stronger solution, it will call for longer time of contact and agitation. It is separated; it is thickened; it is ground to its ultimate size; and it should be given the treatment necessary for itself before it is again combined with the slime. Or rather, it should be given such separate agitation that when later combined with the slime, the strength of solution and time of contact sufficient for the treatment of the slime will also be sufficient to *complete* the treatment of the sand.

We would not recommend separate decantation, because the slime alone would be found difficult to settle readily if the sand were not combined with it to assist settlement; moreover, there would be no advantage in decanting the two parts separately as the process would be identical with each.

### Agitator in Tube Mill—Classifier Circuit

The mill arrangement on this basis would place the sand agitators following the tube mills. The pulp would have to be elevated; but it has to be elevated anyway, either by some elevator, pump, or air-lift, to the classifier; or by the classifier itself and a big scoop on the tube mill, if a closed-circuit system be followed. And if it were the custom to send the pulp direct from the tube mill to the thickener, the pulp could flow into and from the agitator set at a low level, without consuming any appreciable amount of fall in addition.

In any case, the top of the agitator would be such that the overflowing pulp could flow to the classifier. The closed circuit would still be maintained; the pulp sufficiently ground would have received its due agitation and would join the overflow of slime from the classifier, and go on to the thickener. The insufficiently ground pulp would be discharged from the classifier and returned to the tube mill, again passing through the agitator.

The elevating of the pulp to the top of the agitator would not be any great addition to what is already being done, and could be accomplished easily by placing an air-lift *inside* the agitator, or in the last of a series of agitators, thereby taking care of the submergence question. Under conditions of present practice we have a classifier set close up to a tube mill, with launders running to and from it on the ragged edge of insufficient fall, and a great, big, unwieldy scoop on the head of the mill. Under the proposed scheme we might have a small, light, cheap scoop on the head of the mill, the discharge flowing by gravity directly into an agitator or a series of them, with an air-lift placed *inside* the last agitator to lift the pulp the few feet necessary to return it to the classifier. As between the two arrangements, give me the latter with the air-lift.

The depth of the agitator can be placed below the discharge of the tube mill, excavating if necessary; or the agitator can be placed in a distant part of the mill if immediate space be not available close by, the pulp elevator being placed before or after the agitator as conditions would indicate.

If the tube mill should discharge into the agitator by gravity, there would also be the advantage of the latter acting somewhat as an equalizer: if the charge were carried a few inches low, the air-lift could be stopped if the classifier had to be shut down temporarily; if the crushing also had to be stopped, the air-lift could be stopped, but the agitation could continue.

Also, but not least, if concentration were practiced, the sand would carry all the concentratable product; it would be in ideal form, thickened but easily diluted to the desired point. The air-lift at the overflow of the agitator could elevate the pulp to such height as would permit of its being passed over tables and still returned to the classifier or to the thickener as might be desired. And as most concentrating tables also classify pulp tolerably well, that sand which had been "slimed" in passing through the tube mill could be cut out and sent directly to the thickener; only the sand really needing regrinding being returned to the classifier.

### Scheme Applicable to All-Sliming Method

These ideas apply to any plant making an "all-slime" product; whether using cones, Esperanza, Dorr, Akins, or any other classifier; Trent, Dorr, or any other agitator; continuous decantation as Dorr has arranged it, or as Trent works it.

With Dorr's arrangement of precipitating the overflow from the first thickener in continuous decantation, this overflow would be enriched by the metal dissolved from the agitated sand; the metal dissolved from the slime in later agitation would still go around through the batteries and ultimately be recovered from the thickener overflow solution as now arranged.

The combined pulp would still pass through the usual first thickener; but the agitators following would be designed to give only the conditions necessary to make the extraction from the slime, this being only a part of the treatment formerly given to the whole combined pulp. The sand agitators would be of capacity for only half or so of the total ore; special treatment could be given this refractory part of the ore; and the solution used on it would be substituted by new solution by the time it reached the second agitators, which of itself would be a benefit.

We believe that this suggested arrangement offers a number of possible advantages: (1) less equipment; (2) weaker solutions and lower chemical consumption of cyanide; (3) earlier recovery of valuable solution; (4) lower grade of solution to be displaced at the tail end of the plant, with consequent reduced loss of dissolved metal; (5) lower mechanical loss of cyanide, because of weaker solutions; (6) lower power consumption to the extent that the agitation in the second agitators would be only for the period found necessary to make extraction on the slime. It is true that the use of power for agitating the sand has been transferred from one set of agitators to another, but the saving lies in not agitating the slime any more than its needs demand.

### Importance of Strength of Solution and Time of Contact

Strength of solution and time of contact seem to stand out as the most important factors in agitation. Volume of solution and substitution of new solution in extended time of agitation, are also factors of importance, but not to the extent of the first two.

It seems to have been determined in general practice that where strong solution and shorter time of agitation give equal results in extraction with weaker solution and longer time of agitation, the latter system is the more economical in the end. It would appear that the higher cyanide consumption due to the use of stronger solutions, with less agitation, is more costly than lower cyanide consumption due to lower strengths used, with more agitation and consequent power cost. At least that seems to be general practice; the universal tendency being to endeavor to bring about the use of lower strength solutions, even though it entail longer time of agitation. What every operator the world over is always trying to do above everything else is—reduce the strength of the working solution. He can trace most of his economies effected to this source. He can allow quite a margin in installation, power consumed, and in many other features, if he can but accomplish a lowering of the strength of his solution. A great saving is always made in the cyanide consumed chemically; solutions do not foul so easily and quickly; and the mechanical loss of cyanide is always less with weak solution as there is less to be displaced before discharging the final tailing.

If operators would consider more the mechanical losses that occur all through the plant in addition to that represented in discharged tailing, they would thereby locate a lot of the trouble experienced in making bullion recovery tally with assay returns.

If any operator takes the faith cure and persuades himself that his shift bosses do not overflow tanks and launders; do not waste solution around pumps and in pipe and valve repairs; do not permit leaks from the bottom of tanks to seep away; he will have to study advanced mathematics to enable him to figure out a method to explain away discrepancies in final results.

The weaker the strength of the working solution the less loss from all these mechanical troubles; also, the dissolved valuable metal circulating around a plant would be less, and the loss from this source would also be reduced.

Proper drainage floors leading all waste to catch basins would recover most of the loss, but how many plants do we find that have all floors cemented, and draining to catch basins?

### Early Recovery of Dissolved Metal

In Dorr's arrangement of continuous decantation he does not precipitate the solution recovered after agitation, but sends it back to the batteries to serve the incoming ore first, and then precipitates it when recovered from the overflow of the first thickener. This is evidently a point evolved to recover the valuable solution as early as possible in the system so that there will be less of dissolved metal to be carried toward the tail end of the plant; and he thereby relieves the decantation tanks of a great part of their most responsible work. At the same time he is putting more dissolved metal into circulation around the plant, and this is subject to the mechanical losses that we have been emphasizing.

With agitation of the sand after regrinding and before thickening, the metal dissolved from this part would be recovered from the overflow of the thickener immediately following. There would, therefore, be no circulating around the plant of this part of the dissolved metal; also, the dissolved metal carried with the pulp from the second agitators to the washing thickeners would be less than ever, with consequent reduction of dissolved metal in the tailing.

The sand being the more refractory, the cyanide for strengthening solution would be added to the head of the tube mill, thus making the tube mill a part of the sand agitating system. This stronger solution would raise considerably the strength of the battery solution that really constitutes the overflow of the first thickener. In all probability this solution accompanying the thickener discharge would still have an excess of cyanide for effecting extraction on the slime. Hence no cyanide would have to be added to the second agitators; weaker solution would be circulating toward the tail end of the plant; and mechanical loss from this source would be reduced.

Another feature that supports this last contention is, that the strengthening of the battery solution in the classifier by the strong solution coming over with the agitated sand, would raise the strength of working solution in contact with the slime while passing through the classifier and the thickener. This would occasion earlier dissolution of metal from the slime, further enrich the thickener overflow and thereby earlier remove more metal from circulation. It would also reduce the work required of the second agitators, and so more than ever reduce the cyanide and dissolved metal to be taken care of at the tail end of the plant.

It may be contended that but few ores are of such a nature that the part we designate as slime would give up its valuable metal under the conditions that we specify. It is a matter of interest that in the Black Hills of South Dakota there are plants operating in which the slime separated at the classifiers is passed through thickeners serving as continuous wash tanks, and *no specific agitation at all* is given this pulp. It gets its agitation while passing through the crushing apparatus. It is of no especial concern at the moment that these Black Hills operators have percolation plants to treat what we here call the "sand" part of the ore. If they should later practice all-sliming they would still separate this same sand as they are now doing, could give it its due agitation apart, and then combine it with the slime and carry out the same treatment that they are now giving the slime.

### Scheme Applicable to New or Existing Plants

The application of this system would present no particular difficulties. In designing a new plant we would have everything more compact and more easily supervised, as the sand agitators and the first thickener would be about on the same level, and close to the tube mills instead of two levels below. Heretofore we have had to concede to the thickener's particular service the fall or depth of its tank, and all the subsequent equipment has had to come below it to make a gravity-flow plant. It is true that with Dorr's arrangement the zinc boxes now come practically on the thickener level or but little below. With our scheme the sand agitators, thickener, and zinc boxes would all come on practically the same level. Below this level would come the combination agitators, and the thickener wash-tanks.

In adding these sand agitators to an existing plant they would have to be placed wherever a location could be found, even at a distance; and it is likely that more elevation would have to be given the pulp, as the distance to and from the agitators would have to be considered in determining the fall of the carrying launders.

This separate agitation of the sand does not involve the use of any particular crushing machinery, the use of any particular classifier, thickener, or agitator, nor the use of any particular decantation or washing system. It would serve only with "all-slime" crushing.

Denver, Colo.

---

**The mineral production of Texas** for 1913 is valued by the U. S. Geological Survey at over thirty million dollars. The state ranks nineteenth among the United States in the value of its mineral production. It ranks second in the production of asphalt and third in production of quicksilver. It holds fourth rank in quantity of petroleum produced. Sulphur production, by methods similar to those used at Sulphur City, La., were begun at Bryan Heights, in Brazoria county, in 1913.

**Imports of artificial dye-stuffs** into the United States have been valued at $10,000,000 annually for each of the past five years. The imports for the year ending June 30, 1914, fell off about 5 per cent in value as compared with previous years. The following table shows the imports for 1914, with the share furnished by Germany.

| | Pounds | Value |
|---|---|---|
| Alizarin and alizarin colors: | | |
| From Germany | 2,593,758 | $833,705 |
| From all other countries | 39,656 | 11,754 |
| Aniline salts: | | |
| From Germany | 2,768,191 | 202,722 |
| From all other countries | 316,276 | 20,006 |
| Indigo: | | |
| From Germany | 7,448,412 | 938,097 |
| From all other countries | 676,799 | 155,129 |
| Coal-tar colors, all other: | | |
| From Germany | ...... | 5,965,537 |
| From all other countries | ...... | 1,275,869 |
| Total values: | | |
| From Germany | ... | $7,940,061 |
| From all other countries | | 1,462,758 |

NOTE—The statistics for indigo include imports of natural indigo from India, which average less than $100,000 worth annually.

# The Possibilities of Hardwood Distillation on the Pacific Coast

BY R. C. PALMER

Chemist in Forest Products
Forest Products Laboratory, Madison, Wis

### Introduction

The interest in the wood distillation industry on the Pacific Coast has been confined in the past entirely to the softwoods, Douglas fir, and western yellow pine. Unfortunately, the history of the commercial attempts that have been made to obtain valuable products for these species has been largely a succession of failures, owing to a variety of causes.

The fact that softwood distillation is not a well established industry, the inability to secure commercial quantities of suitable raw material at favorable prices, and the more or less experimental nature of plants that have been erected have been in general the main causes for these failures. The products which these plants attempted to recover from the western softwoods were turpentine, tar, tar oils, and charcoal, and in several cases alcohol and acetate of lime, depending on the process employed.

It is well known that the yields of the three last named products, charcoal, alcohol, and acetate, are considerably less from softwoods than from hardwoods, and that the yield of these products is sufficient to make the distillation of certain species of hardwood a perfectly feasible commercial enterprise.

In view of the importance to other industries on the Pacific Coast, of securing wood-distillation products, particularly charcoal and wood alcohol, without paying freight from plants in the middle western or eastern States, and because of the very limited possibilities of securing these products economically from softwoods, the United States Forest Service conducted investigations during the fall and winter, 1913-14, both at the Forest Products Laboratory, Madison, Wis., and on the coast, to study the feasibility of establishing a small hardwood distillation industry in that locality.

The results of this investigation are summarized in this paper.

### Hardwoods Available

There is a large variety of hardwoods native to the Pacific Coast, including birches, maples, and oaks. There are some fifteen species of oaks alone, besides several imported species such as Eucalyptus, acacias, madrone, etc.

None of the native hardwoods occur in pure stands, however, and very few in large enough stands mixed with the softwoods to make them of importance as raw material for a distillation plant.

From the standpoint of the species with quantities sufficiently centralized only two or three appear promising: (1) the tanbark oak (Quercus densiflora); (2) the California black oak (Quercus Californica), with the scattering "white oaks"* that occur with it—such as Oregon post oak, Chinquapin oak, Canyon live oak; (3) possibly Eucalyptus.

The present investigation has considered only the tanbark oak and the black oaks. It seems probable that Eucalyptus will compare favorably with the oaks as regards yields of by-products, but the quantities available are too small to be considered for the present. Eucalyptus gives an especially high grade charcoal which brings a high price per ton in limited quantities and can, therefore, be best considered only for the production of charcoal.

---

*These oaks occuring in scattered stands as well as a number of hardwoods such as gray birch, Oregon maple, alder, cottonwood, etc., probably all have a value for making charcoal alone where few charcoal kilns can supply the immediate demands of a community. Since softwoods can compete with the hardwoods in the manufacturing of charcoal alone, these hardwoods are obviously eliminated from the list of possibilities.

### Tanbark Oak

Tanbark oak is best known because of the high value of its bark for the production of tannin. However, only the bark is used, and the tree is generally allowed to rot in the woods. Utilizing the wood of this tree after being abandoned by the bark peelers is an economic problem of considerable importance.

This oak occurs principally in the redwood* belts of Mendocino and Humboldt counties, California, forming a band along the inland side of the redwood covering what is called the "Bald Hills." The best stands are not in the main redwood forests, but only on the summits above the redwood, particularly on the inner summits and ridges. Here the trees are most abundant and of large size and running probably as high as 15 to 20 cords of wood per acre; with an average of about 7 to 10 cords.† This stand is light compared to the usual yields of cordwood per acre for distillation plants, but as this same region will be logged for the great redwood forests, there is a possibility of securing the tanbark wood in connection with these logging operations.

The logical place for distillation plants using the tanbark oak is in connection with the redwood lumber mills cutting in this region, and where mills are in the coast towns, thus providing shipping facilities for the products either by rail or water.

### California Black Oak

The California black oak occurs in a much more solid stand than the tanbark oak. The range of this oak is comparatively wide, but the accessible timber is located in a small area of about 40 square miles in Shasta County, California, north and west of the Pitt River, and along its tributaries. This oak occurs in largest quantities on the west slopes and flats of the foothills west of the Sierra Nevada range. It is estimated that in a small area beginning witih Reynolds Basin in the Shasta National Forest, where the stand will average 25 cords per acre, south and west for about 20 miles between the Pitt River and Squaw Creek, there are 300,000 cords of this oak. The black oak would make practically no saw timber, and only very scattered stands of western yellow pine and red and white fir are found with the oak. This species of hardwood from the standpoint of quantity and general characteristics would be available to a distillation plant located at a point on the Pitt River most accessible to the Portland division of the Southern Pacific Railroad.

### Laboratory Tests on Tanbark and Black Oaks

Tests to determine the yields of products from California tanbark and black oaks compared to the species commonly used for distillation purposes, beech, birch, and maple, were made at the Forest Products Laboratory. The results of these tests are given in Table 1. The yields of wood alcohol, acetate of lime, and charcoal from Douglas fir and western yellow pine are also given for comparison.

From the figures given in the table the average yields from beech, birch, and maple are about 1050 pounds charcoal, 192 pounds acetate, and 10.6 gallons crude alcohol per cord. On this basis the tanbark oak would be expected to yield about the same in charcoal, 20 per cent. more acetate, and 8 per cent more alcohol than the species commonly used.

Small trunks of black oak high in sap would give about 5 per cent more charcoal, the same acetate, and 11 per cent less alcohol than the standard species. It is apparent that for the black oak the greater the per cent of sapwood such as in limbs, the higher the yields, since small limbs* give 30 per cent greater yields in charcoal, 40 per cent greater yields in acetate, and 18 per cent more alcohol than beech, birch, and maple. The possibility of securing all black oak as limbs or other forms high in proportion of sapwood would, however, not be great.

TABLE 1—COMPARATIVE YIELDS OF WOOD ALCOHOL, ACETATE OF LIME, AND CHARCOAL, PER CORD* BASED ON LABORATORY TESTS†

| Species | Charcoal | Acetate of Lime | Crude (82%) Wood Alcohol |
|---|---|---|---|
| | Pounds | Pounds | Gallons |
| Beech.............. | 1100 | 185 (Heartwood)††<br>200 (Slabs) | 12 (Heart)<br>11 (Slabs) |

| Black oak.......... | 1100 (Slabs)<br>1400 (Limbs) | 190 (Slabs having high per cent sapwood)<br>270 (Limbs all sapwood) | 9.4 (Slabs having high per cent sapwood)<br>12.4 (Limbs) |
| Douglas fir......... | 800 to 900 | 60 Stumps<br>80 Slabs | 3 Stumps<br>4.3 Slabs |
| Western yellow pine. | 750 to 850 | 60 to 80 | 2 to 4 |

*One cord is taken as 90 cubic feet of solid wood containing 15% moisture.

†Results are average of several distillations, each distillation on about 80 pounds of wood.

††In a number of species it has been found that the higher the proportion of sapwood the higher the yields of acetate of lime. For this reason the different forms of wood are given.

From the laboratory tests, therefore, both the tanbark and black oaks, especially the former, compare very favorably with the species or hardwood used in other localities.

### Commercial Tests

The laboratory tests on black oak were followed by a commercial distillation of 7 cords at the wood distillation plant of the Noble Electric Steel Company, Heroult, California. This plant was not designed for hardwood distillation, but had previously operated on western yellow pine with practically no success.

Unfortunately the plant was not especially fitted for the best results from hardwood distillation and the black oak tested consisted of split cordwood from large trees and contained practically no limb wood or forms high in proportion of sapwood.† The commercial yields obtained are given in Table II. The yields per cord from one test (2 cords) of a mixture of scrub oaks and canyon live oak classed as "white oak" are also given.

TABLE II—YIELDS PER CORD COMMERCIAL DISTILLATION OF CALIFORNIA BLACK OAK

| Species | Alcohol, Crude, 82% | Gray Acetate of Lime | Charcoal |
|---|---|---|---|
| | Gallons | Pounds | Pounds |
| Black oak .. | 8.7 | 117 | 1140 |
| White oak | 8.7 | 135 | 1090 |

The commercial yields on black oak indicated about the same charcoal, 8 per cent less alcohol, and 23 per cent less acetate of lime than the laboratory tests. These data are, however, not strictly comparable because of the difference in the character of the wood tested in the laboratory, and in the plant.

In spite of lower yields obtained commercially than was expected, the possibilities of commercial operation are favorable, even if better yields are not obtained with better wood and plant conditions.

---

*Forest Service Bulletin 75 "California Tanbark Oak."

†According to estimates in Forest Service Bulletin 75, the total stand is about 675,000,000 board feet, which would be at least 500,000 cords of wood suitable for distillation

*These figures are based on cords of equal volume of solid wood. In actual practice a stacked cord of limbs would contain much less volume than split wood which would reduce these proportions.

†In addition to difference in form the commercial wood was either very green or badly water soaked at the time of making the tests.

## General Commercial Conditions

### QUANTITY OF RAW MATERIAL

The possibilities of establishing a hardwood distillation industry on the Pacific Coast must be confined to fairly large and well concentrated blocks of timber suitable for cordwood. The destructive distillation of hardwoods for the manufacture of charcoal, wood alcohol, and acetate of lime, is a highly technical industry requiring rather expensive equipment of a standard design. For this reason, sufficient raw material should be available to insure 15 to 20 years life of a plant.

A plant with a capacity of 36 cords per day is about as small as can be economically operated. This would require a stand of hardwood containing from 150,000 to 225,000 cords of wood and, in addition, it is evident that the material cannot be scattered over too wide an area.

### COST OF BUILDING AND OPERATING ECONOMIC PLANTS

The cost of building and equipping efficient hardwood distillation plants would be from $2,500 to $3,000 per cord per day capacity. A 36-cord plant would, therefore, cost between $90,000 and $110,000.

This applies to the standard oven type of plant in which each oven or retort holds from six to eight cords and the wood is carried in small cars, each carrying about two cords. Such a plant would be completely equipped to manufacture gray acetate of lime and wood alcohol suitable for denaturing grain alcohol.

On account of the wide variation in cost of labor, freight rates, etc., in different localities, and because of different conditions of efficiency or supervision, etc., cost data on the operation of hardwood distillation plants cannot be given which will apply to all cases.

The relative weights of the different items of the cost of operating plants are, roughly, as follows:

| | |
|---|---|
| Raw material (wood in retorts) | 40 to 50 per cent of total cost |
| Labor | 15 " 25 " " " " " |
| Fuel for distilling and refining | 10 " 20 " " " " " |
| Maintenance (repairs overhead, etc.) | 15 " 25 " " " " " |

The raw material is by far the largest single item of expense and especial attention to economical handling of wood is, of course, essential. Every time a cord of wood is handled it adds about $0.50 to its cost. The average cost of wood in plants in the Middle West and East is about $3.50 per cord in the retorts. The wood on the Pacific Coast would probably cost more than this as (1) it is generally less accessible, (2) it is not as well concentrated, and (3) the cost of labor is higher. Where eastern labor costs $1.75 per day, the same labor will cost $2.25 per day in California.

The choice of fuel for distilling the wood and refining the products is an important consideration. Probably the best condition as regards fuel is in case the plant is operated in connection with a saw mill where ample wood waste is available for this purpose which would otherwise be sent to the trash burner. The cost of fuel is then only the cost of conveying the waste to the retorts and maintaining the fire in the fire boxes. This cost should not be over $1 per cord of wood distilled. Where wood waste is not available in California, crude oil is probably the best fuel. The cost per cord would be, however, appreciably higher than wood waste fuel, costing probably from $1.25 to $1.50. These fuel costs are not much higher than in other places using comparable fuels.

In spite of the increase in cost of operation due to higher labor and wood costs in California over other localities the total cost of operation should apparently not be over $9.50 per cord as compared to about $8 to $8.50 per cord in other localities.

### VALUE OF PRODUCTS

Higher costs of operation combined with lower yields of products as in the case of black oak would appear to be too great a handicap for profitable operation on this species of wood, but while the yields of alcohol and acetate from black oak may be somewhat lower than from beech, birch, and maple, the charcoal is slightly higher, and in addition charcoal is generally worth from 40 to 60 per cent more in California than in the localities where the charcoal from the standard distillation species is sold.

The effect of this difference in charcoal value in bringing up the total income from products is seen in the following calculation:

YIELDS FROM BEECH BIRCH, AND MAPLE, AND VALUE OF PRODUCTS IN EASTERN STATES AT PRESENT TIME

| | | | |
|---|---|---|---|
| 10.5 gal. 82% alcohol at 26c | = $ 2 73 | or 8¼ gal. 95% at 47 | = $ 3 87 |
| 195 lb. acetate at 1.5c | = 2 92 | | = 2 92 |
| 1050 lb. charcoal at $7 per ton | = 3 67 | | = 3 67 |
| Total | $9 32 | | $10 46 |

YIELDS FROM BLACK OAK AND VALUE OF PRODUCTS IN CALIFORNIA

| | | | |
|---|---|---|---|
| 8.7 gal. 82% alcohol at 26c | = $ 2 26 | or 6.75 gal. 95% at 47c | = $ 3 17 |
| 147 lb. acetate at 1.5c | = 2 20 | | = 2 20 |
| 1140 lb. charcoal at $10 per ton | = 5 70 | | = 5 70 |
| Total | $10 16 | | $11 07 |

In the case of tanbark oak there is every reason to believe that the yields of alcohol and acetate will be greater rather than lower than beech, birch, and maple.

Ten dollars a ton is a minimum figure for charcoal when sold for domestic fuel in coast states. Its average value is probably nearer $15 a ton for this purpose. The market value of alcohol and acetate cannot be expected to be higher than in other localities since the same markets are supplied in both cases.

### MARKET FOR PRODUCTS

*Charcoal.*—The possibilities of creating a demand for charcoal for domestic fuel are apparently excellent, especially in California, where both wood and coal are very high. In other localities where the manufacturer has done a little advertising, charcoal has supplanted wood blocks and kindling wood for making quick hot fires.

With the development of metallurgical processes another large market may be created for charcoal, although for this purpose the value is generally less than for domestic fuel.

Charcoal is difficult to ship for long distances, so the markets will necessarily always have to be somewhat local.

*Acetate of Lime and Alcohol.*—There is at present no acetate of lime used on the Coast, but home production of acetate might encourage the establishment of a small acetic acid industry to supply the white lead manufacturers.

The total consumption of wood alcohol on the Pacific Coast is at present about 1200 barrels or 60,000 gallons. A small part of this is consumed in wholesale drug houses but the largest proportion is used for the denaturing of grain alcohol. This alcohol is at present being supplied from eastern plants at 8 cents freight cost over New York quotation. There seems to be little doubt but that any plant in California could successfully compete in this home market.

With the opening of the Panama Canal the largest opportunity for marketing both alcohol and acetate of lime is with the export trade.

The following tables, taken in part from the yearly report of the U. S. Bureau of Foreign and Domestic Commerce, 1912, show the exports of these products to various countries from the United States for several years past:

EXPORTS OF ALCOHOL (GALLONS)

| Country | 1908 | 1909 | 1910 | 1911 | 1912 | 1913 |
|---|---|---|---|---|---|---|
| Japan....... | 280 | 2,350 | 49,829 | 36,490 | 50,302 | |
| Canada...... | ..... | 209 | 4,539 | 2,486 | 30,799 | ....... |
| Germany..... | 781,000 | 568,000 | 654,000 | 974,000 | 815,000 | ....... |
| Netherlands.. | 45,000 | ....... | 173,000 | 471,000 | 102,000 | ... |
| All Europe... | 1,937,000 | 1,085,000 | 1,269,000 | 1,912,000 | 1,474,000 | 1,837,000 |

EXPORTS OF GRAY ACETATE OF LIME (POUNDS)

| Country | 1908 | 1909 | 1910 | 1911 | 1912 | 1913 |
|---|---|---|---|---|---|---|
| Japan... | ........ | 2,200,000 | 3,600,000 | 5,800,000 | 5,300,000 | ........ |
| Belgium... | 26,200,000 | 25,800,000 | 27,100,000 | 22,900,000 | 28,100,000 | ........ |
| Germany... | 17,200,000 | 18,800,000 | 14,900,000 | 16,700,000 | 16,700,000 | ........ |
| Netherlands... | 10,800,000 | 11,600,000 | 10,500,000 | 15,300,000 | 11,500,000 | ........ |
| United Kingdom. | 2,100,000 | 1,700,000 | 1,800,000 | 2,800,000 | 600,000 | ........ |
| Canada....... | 50 | 241,000 | 15,000 | ....... | 126,000 | ........ |
| Total....... | ....... | 66,550,000 | 63,687,000 | 70,191,000 | 69,235,000 | 80,597,000 |

Japan probably offers the best opportunity for export trade for wood alcohol. The wood alcohol consumption is, however, rather small. At present both these products go to Japan via the Suez Canal. Eastern plants will, no doubt, compete in this market through Panama, but in that case the European markets will be as open to any plant in California as the Japanese markets will be accessible to plants in Michigan or Pennsylvania.

A 36-cord plant would produce in a 300-day year, approximately 75,000 gal. of 95 per cent alcohol, and between 1½ and 2 million lb. of gray acetate.

From the standpoint of the present market conditions it is doubtful, therefore, if the establishing of more than one or two small plants in California would be advisable.

---

**Lead sheets and pipes** of American manufacture are in demand in European countries, according to the *Daily Trade and Consular Reports* issued by the Department of Commerce at Washington. Drawn steel tubes and lap-welded tubes of iron or steel also are needed.

**A copper-leaching plant** of 20-tons daily capacity is reported to have been placed in operation at the Mason Valley smelter, at Thompson, Nevada, for the treatment of certain oxidized ores from the Yerington district.

**Flotation of copper ores** according to a new process attributed to John D. Fields is to be tested at the mill of the Ohio Copper Co., at Lark, Utah, and at some other copper concentrators.

**"Salting" of Radium Ore.**—One or two instances have recently come to light in which it is thought that an attempt was made to give a fictitious radium value to uranium-bearing material. Suspicion exists that uranium residues from which radium has been extracted, have been mixed with carnotite, thereby raising the grade of the material as to uranium, so that when the radium value of the ore was determined from its uranium content, as has been customary, it would appear much higher than it is. The possibility of deception by this practice may result in abandoning the indirect determination of radium in favor on the more accurate and direct electroscopic measurement.

**Diamonds** have become a drug on the market since the European war broke out. The Diamond Syndicate has terminated its contract with the De Beers company in South Africa, and the mines of the latter have been closed.

# Indeterminate Cases in Mixing Ores for Calculation of Furnace Charges

BY REGIS CHAUVENET

## Mixing Ores to Secure a Required Percentage of Any Constituent

Before taking up the actual calculation for slag composition in a mixture of several ores, it may be well to show how to mix ores of given composition in order to secure a certain (required) percentage of any given constituent.

First, let there be two ores; the problem is so simple that it hardly requires elucidation. The requirement is easily formulated and the formula reduced to the following rule, viz.:

*Take weights of the two ores in inverse ratio to the differences between their assays and the (required) assay of the mixture.*

*Example.* (*a*). Mix two ores containing, respectively, 40 per cent and 8 per cent of a given constituent, so that the mixture shall contain 16 per cent.

(1) The larger per cent less the required per cent is $40 - 16 = 24$.

(2) The required less the smaller per cent is $16 - 8 = 8$.

Now take weights of the two ores *inversely* as these figures, i.e., take eight parts of No. 1 and twenty-four parts of No. 2. (In this instance reducing to simpler ratio, as $8:24 = 1:3$, take one part of No. 1 and three parts of No. 2.)

*Proof.* 100 lb. of No. 1 contains.....40 lb. metal
300 lb. of No. 2 contains.....24 lb. metal

400 lb. mixture contains.....64 lb. metal.

Then 64 is 16 per cent of 400, as required.

If there are three ores to be mixed there is no definite solution, unless one of the three happens to contain the given constituents in just the required proportion. In that case it is evident that the proper proportions of the other two ores having been adjusted, any weight whatever added of the third ore will not change the percentage of the given metal.

However, if no one of the three contains the required percentage, then if Nos. 1, 2 and 3 represent respectively the minimum, intermediate and maximum percentages, and since the required percentage must obviously be greater than in No. 1 and less than in No. 3, we have an "indeterminate" mixing problem, *"if all three ores are to be used.* For the required percentage must lie either between Nos. 1 and 2 or between 2 and 3, so that it can never be necessary to use all three ores, so far as the mere obtaining of this percentage is concerned.

By limiting the weights of one lot of ore to a certain figure, or by stipulating a certain proportion as between certain classes of ore, we may reduce the problem to a "determinate" one. Cases of this kind are exceptional, but it is well to have a ready method for figuring on them.

*Example.* (*b*) We have three ores assaying 39, 24 and 8 respectively. (N. B. It makes no difference whether the figures represent percentages or ounces to the ton.) We want 16 (per cent or ounces) in mixture. Obviously this may be obtained either from Nos. 1 and 3 or from Nos. 2 and 3. But suppose we are compelled to use both 1 and 2 and the latter in twice the proportion of the first.

What proportions of the three ores in the mixture? Take 100 lb. of No. 1 as the basis.

---

[1] Calculation of Furnace Charges, by Regis Chauvenet. This Journal, Jan., Feb., Mar., Apr., and June, 1912.

[2] Ibid.

| | |
|---|---|
| 100 lb. of No. 1 contains................ | 39 |
| 200 lb. of No. 2 contains................ | 48 |
| —— | — |
| 300 lb. of mixture contains............. | 87 |

The mixture then contains $\frac{87 \times 100}{300} = 29$ per cent or ounces. The mixture now constitutes one element of the calculation, and we proceed to mix it with enough of No. 3 to get the final required figure (16).

$$29 - 16 = 13 \text{ and } 16 - 8 = 8.$$

We have then to take 8 units of the "mix" and 13 units of No. 3.

Suppose we have to make up an "even" weight of the total mixture. Go back to original ore parts, and proportionate to (say) 1000. We find for the three required parts in 1000 lb., No. 1, 127; No. 2, 254, and No. 3, 619 lb. This may be proved as in the former example, ex. gr.

$$\left.\begin{array}{l} 127 \times 0.39 = 49.53 \\ 254 \times 0.24 = 60.96 \\ 619 \times 0.08 = 49.52 \\ \overline{1000} \qquad\quad \overline{160.01} \end{array}\right\} \text{160 is 16 per cent of 1000.}$$

### Mixing Ores for a Definite Slag

These little "mixing" cases are thrown in here merely as incidental to cases of mixing ores for a definite slag. We have shown an "equation" method in previous articles,[1] for any two ores and a limestone, illustrating that unless the problem is impossible for sheer lack of proper constituents in the data, it presents no especial difficulty. We now put the case of three ores and a limestone. The latter is assumed in all the examples to contain:

| | |
|---|---|
| Silica ...................... | 10 per cent |
| Lime (CaO) ............... | 50 per cent |

As this is intended for an arithmetical illustration only, we simplify it by making the supposed analyses ideal to an extent not to be expected in nature. The ores are supposed to have been "cleared" of the matte, i.e., that has been taken out (by calculation) and nothing is given in the analyses except what enters the slag.

An indeterminate case is one in which several mixtures may bring about the required condition i.e., a slag of the stipulated composition.

Generally, any problem to which there are several answers, or an indefinite number of answers, may be called indeterminate.

Algebraically, an equation with two unknown quantities ($x$ and $y$) with no further condition or equation to assist, is called indeterminate. The same term may be applied to two equations involving three unknown quantities, or, in short, to any set of equations presenting a greater number of unknowns than there are equations.

There are cases in which although but one rational answer is possible the statement is nevertheless indeterminate in form. These are not considered. They could hardly occur in metallurgical practice. Discussion of a few cases in which several mixes alike meet the general requirement, will be sufficient. In accordance with our precedents, there are made extremely simple.

*Example.* (a) We have three ores analyzing, as to slagging constituents, as follows:

| | $SiO_2$ | Bases | Lime (CaO) | |
|---|---|---|---|---|
| Ore No. 1...... | 50 | 30 | .. | per cent |
| Ore No. 2...... | 40 | 20 | .. | " " |
| Ore No. 3...... | 30 | 10 | .. | " " |
| (Limestone as above) ....... | 10 | .. | 50 | " " |

*Ore* charge is to be 1000 lb. Requirement for the slag as below, viz:

| | |
|---|---|
| Silica ........................ | 50 per cent |
| Bases from the ore mixture.. | 25 " " |
| CaO from the limestone...... | 25 " " |
| | —— |
| | 100 " " |

(We drop our usual practice of assuming 100 lb. *for one of the ores.* Note that the charge of 1000 lb. does not here include the flux (limestone).

As no one ore is fixed in weight, but the sum total of the three alone is a fixity, the weight of any one becomes an "unknown."

Let $100x$, $100y$ and $100v$ represent respectively the weights in pounds of ores 1, 2, 3 and of the limestone. The last ($100v$) is inserted to give generality in form since $v$ may be determined without formal calculation.

The constituents are now represented by the same figures as their respective percentages, all with the unknown letters annexed, as below. (Reason for taking $100x$, etc., instead of $x$ is to obviate necessity of fractions. Coefficients for $x$, $y$ and $z$ are now taken directly from table of analyses.)

| | $SiO_2$ | Bases | CaO |
|---|---|---|---|
| No. 1 ............. | $50x$ | $30x$ | ... |
| No. 2 ............. | $40y$ | $20y$ | ... |
| No. 3 ............. | $30z$ | $10z$ | ... |
| Limestone ......... | $10v$ | ... | $50v$ |

This method of setting forth the constituents entering into a slag calculation has been given at length in this journal in former articles.[2] It suffices to call attention to the fact that we may now select expressions for silica, base or lime directly from the analyses as written above, i.e., with the respective letters annexed, remembering that the total quantity of any one constituent of the charge is represented by $100x$, etc., as stated above.

There are three equations on the conditions.

$$100x + 100y + 100z = 1000 \text{ (Or; } x + y + z = 10\text{)} \qquad (1)$$

$$30x + 20y + 10z = 50v \text{ (i.e., bases = CaO)} \qquad (2)$$

$$50x + 40y + 30z + 10v = 30x + 20y + 10z + 50v \qquad (3)$$

Equation (3) expresses the condition that the silica equals all the bases, lime included. No. 3 reduces to $x + y + z = 2v$.

Hence by (1) $2v = 10$ and $v = 5$. Limestone therefore $(100v) = 500$ lb.

### Quantity of Lime Independent of Proportions of the Three Ores

This shows that the lime addition is independent of the proportions of the three ores. This is no general proposition for similar cases, but merely an incident in the present conditions. It often happens, however, that some fact like the above (viz: independence of the lime addition) is first discovered analytically.

The limestone being thus found to be the same for any possible mixture under the conditions, reduce the remaining equations. We find:

$$\text{(a) } x = 5 + z \text{ and (b) } y = 5 - 2z$$

Here is the "indeterminate" condition, viz: two equations with three unknown quantities. Algebraically, this indicates an indefinite number of correct solutions. In fact, it is a case in which the two unknowns in these final equations become variables. Assume a value for one of them, the other must, of course, assume a corresponding value. Discussion of the maximum and minimum values of each of these unknowns is exceedingly simple. As $z$ occurs in both of the equations, let us start with it.

(a) shows that 0 is a possible value of $z$ (minimum).

(b) shows that with $y = 0$, $z$ has its maximum value of 2.5

Substituting in (a) we find $x$ has a maximum value of 7.5 and a minimum value of 5. (That is, the ore No. 1 may run from 750 down to 500 lb., but not less.)

Substiuting in (b), we find that $y$ has a maximum value of 5, minimum of 0. We could eliminate $z$, getting $2x + y = 15$. Then $y = 0$ makes $x = 7.5$, and any value for $x$ less than 5 violates the data. But this would save no time, as $z$ would have to be brought in again.

Tabulating these various cases, and writing the values multiplied by 100 so as to represent actual pounds of ore or flux, we have

| | Maximum | Minimum |
|---|---|---|
| Ore No. 1, lb...... | 750 | 500 |
| Ore No. 2, lb...... | 500 | 0 |
| Ore No. 3, lb...... | 250 | 0 |

(*Limestone, always* 500 *lb. for any mixture.*)

We see, then, that ore No. 1 must always be used, and with it, some portion of No. 2 or No. 3 or both, according to the weight of No. 1 taken. Any violation of the equations violates also the slag condition, as may easily be shown.

Take maximum of No. 1; No. 2 now goes to its minimum, i.e., zero. But No. 3 goes to its maximum, 250 lb.

Take minimum of No. 1; No. 3 now goes to its minimum (zero), while No. 2 goes to its maximum, 500.

In all other cases, viz.: with No. 1 somewhere between maximum and minimum, all three of the ores enter the mixture. Assume any value between limits for $x$ then substitution in equations (2) and (3) gives values to $y$ and $z$.

*Examples under each ease.*

(*a*) Ore No. 1: take maximum weight of same. Calculate bases and silica. (No. 1 = 750 lb.; No. 2 = 0; No. 3 = 250 lb.; total = 1000 lb.)

| | $SiO_2$ | Bases | CaO | |
|---|---|---|---|---|
| From ore No. 1..... | 375 | 225 | ... | lb. |
| From ore No. 2..... | 0 | 0 | ... | " |
| From ore No. 3..... | 75 | 25 | ... | " |
| Limestone .......... | 50 | ... | 250 | " |
| | 500 | 250 | 250 | " |

(*b*) Ore No. 1: take minimum weight.

No. 1, 500 lb.; No. 2, 500 lb.; No. 3, zero.

| | $SiO_2$ | Bases | CaO | |
|---|---|---|---|---|
| From ore No. 1..... | 250 | 150 | ... | lb. |
| From ore No. 2..... | 0 | 0 | ... | " |
| From ore No. 3..... | 0 | 0 | ... | " |
| From limestone .... | 50 | ... | 250 | " |
| | 500 | 250 | 250 | " |

(*c*) Ore No. 1; take *any weight intermediate* the maximum and minimum.

No. 1, 700 lb.; No. 2, 100 lb.; No. 3, 200 lb. These figures are found by substituting in (a) and (b).

| | $SiO_2$ | Bases | CaO | |
|---|---|---|---|---|
| From No. 1........ | 350 | 210 | ... | lb. |
| From No. 2......... | 40 | 20 | ... | " |
| From No. 3......... | 60 | 20 | ... | " |
| From limestone ..... | 50 | ... | 250 | " |
| | 500 | 250 | 250 | " |

In the last case we assumed, arbitrarily, that we should take 700 lb. of No. 1. But as this figure is between the limits (750 maximum and 500 minimum) it must lead to correct results under the conditions. Note that these conditions are satisfied in every case—i.e., silica always equal to bases, and CaO always equal to bases from the ores. The problem is thus reduced to finding maximum or minimum weight which can be used of three given ores. It could be used to increase or decrease the use of certain ores, according to supply or cost.

Novices in algebraic statement often attempt to get as many equations as there are unknown quantities, in an indeterminate case. For instance, another equation which in reduced form would read:

$$5x + 4y + 3z = 45$$

could be taken to represent the condition that silica = twice CaO. But this is already implied in the equations above, so that in eliminating $x$ we merely regain the old form: $y = 5 - 2z$.

### Calculation Based on Assumption of One Hundred Pounds of Principal Ore

In calculating furnace charges for slags, we prefer to assume 100 lb. for the leading ore, and adjust the other additions to that figure. Texts on slag calculation differ in this respect; there are those who seem to prefer an assumption for *weight of total charge* (i.e., all the ores and fluxes, but not including the fuel).

In the following example we adopt the method that has always seemed both easier and more logical to us. It is, of course, a mere matter of convention. But it is such an easy matter, having figured for the 100-lb. basis, to pass to any other basis, that the method assuming total charge for the basis of calculation is no longer in favor.

If in any calculation of this kind a value with minus sign should be obtained it is, aside from errors of computation, an indication of the fact that you are attempting to reconcile incompatibles. Inspection of analyses will often show in advance that no mixture of the given components can give the desired result.

To illustrate the above, take the following case: We have three ores with analyses of slagging constituents annexed as below:

| | Silica | FeO | Other bases |
|---|---|---|---|
| Ore No. 1...... | 40 | 10 | 30 per cent |
| Ore No. 2...... | 10 | 60 | 10 " " |
| Ore No. 3...... | 20 | 10 | 40 " " |

Assuming that these can be mixed for "self-fluxing," i.e., without the addition of any limestone, we demand a slag of the following composition, viz.:

Silica, 40 per cent. Iron oxide (FeO), 35 per cent. Other bases, 25 per cent.

As basis for the ore mixture, take 100 lb. of No. 1 ore. Let quantities of ores Nos. 2 and 3 be represented by $100x$ and $100y$ respectively.

We have now as expressions for constituent parts the following:

For $SiO_2$; $40 + 10x + 20y$
For FeO ; $10 + 60x + 10y$
For base; $30 + 10x + 40y$

The 40, 35, and 25 required percentages reduce to ratio 8, 7 and 5.

$7(40 + 10x + 20y) = 8(10 + 60x + 10y)$

Ratio of $SiO_2$ to FeO.

$5(10 + 60x + 10y) = 7(30 + 10x + 40y)$

Ratio of FeO to bases.

The equations present no difficulties in elimination, but having solved for $x$, which we find = 0.45 +, we find on substituting that *y comes out minus.*

Inspection of the analyses, in fact, shows that there is so much iron oxide in No. 2 ($100x$) that we cannot simultaneously get iron low enough and base high enough, while No. 3 ($100y$) has so high a base that it upsets all attempts to adjust the three to the requirements. A trial of any two of the ores will show that the condition is incompatible with the composition.

*Example* (*b*). We give another example of the "indeterminate." The limestone, as indicated in the first place, remains the same, viz.: $SiO_2$ = 10 per cent, CaO = 50 per cent.

| | $SiO_2$ | FeO | |
|---|---|---|---|
| Ore No. 1 | 40 | 10 | per cent |
| Ore No. 2 | 30 | 20 | " " |
| Ore No. 3 | 10 | 30 | " " |

Calculate in this case, the ore charge on the basis of 100 lb. taken of No. 1. *Slag to have composition:* $SiO_2 = 30$ per cent, $FeO = 40$ per cent and $CaO = 30$ per cent; the latter, of course, has to come entirely from the limestone. As before, let $100x =$ lb. of No. 2 ore, $100y =$ lb. of No. 3 ore, and $100z =$ lb. of limestone. Collect expressions for $SiO_2$, FeO and CaO as usual, and equate according to the slag condition.

We cannot obtain more than two independent equations. A few paragraphs back we said that novices often try to get as many equations as there are unknown quantities. Let us try here. We have:

$$\text{Total } SiO_2 = 40 + 30x + 10y + 10z$$
$$\text{Total FeO} = 10 + 20x + 30y$$
$$\text{Total CaO} = 50z$$

Since silica is to equal lime we equate these expressions (1) as FeO is to CaO as 4:3 we put that ratio into (2). Finally as $SiO_2$ is to FeO as 3:4 we embody that ratio in (3).

$$40 + 30x + 10y + 10z = 50z \qquad (1)$$
$$3(10 + 20x + 30y) = 4 + 50z \qquad (2)$$
$$4(40 + 30x + 10y + 10z) = 3(10 + 20x + 30y) \qquad (3)$$

These equations are all divisible by 10. It will be convenient to keep (1) for reference in the form:

$$4 + 3x + y = 4z \qquad (1)$$

The fallacy is in supposing that we have three independent conditions. But, in fact, one condition is implied by the other two.

To divide by 10 and eliminate $x$ is a very trivial operation. We then arrive at the amazing equation:

$$1 = 0$$

or some other absurdity according to the elimination. In short, having made a false assumption and tried to prove it true, we land nowhere.

Throwing away equation (3) we return to (1) and (2) which with $z$ eliminated gives us:

$$4y - 9x = 17.$$

Here $y$ and $x$ are increasing functions. As $y = 0$ gives *a minus value for* $x$ it is not possible. But $x = 0$ gives $y = 4.25$ as minimum value for $y$.

This indicates that using 100 lb. of ore No. 1 (as assumed) we may discard ore No. 2 entirely, and take 425 lb. ($100y$) of ore No. 3. The limestone is found by using the reference form of equation (1) above. We get $4z = 8.25$; $z = 2.062$, i.e., limestone ($100z$) 206.2 lb. Our slag figures then as below, ore No. 2 being omitted.

| | $SiO_2$ | FeO | CaO | |
|---|---|---|---|---|
| From ore No. 1 | 40 | 10 | ..... | lb. |
| From ore No. 2 | 42.5 | 127.5 | ..... | " |
| Limestone | 20.6 | ..... | 103.1 | " |
| | 103.1 | 137.5 | 103.1 | |

10 per cent of 425 = 42.5; 30 per cent of 425 = 127.5 (on ore No. 3).

10 per cent of 206 = 20.6; 50 per cent of 206.2 = 103.1 (on limestone).

This proof is perfect, for the three figures 103.1, 127.5, and 103.1 are exactly in the ratio required, i.e., 3:4:3.

How is it that the silica of the limestone adjusts itself to the summation? Answer: It was adjusted in the original statement, and having been involved in equation (1) no subsequent transformation could take it out.

Still retaining our supposition of 100 lb. of ore No. 1 as the basis of our mixture, how can we work in any portion of ore No. 2, if it be desired to make use of that material? Evidently by taking more of No. 3 than the minimum 425 lb. That is, if we assume a value for $y$ greater than the minimum, $x$ becomes a positive quantity. Let us, for example, assume that we shall add 500 lb. of No. 3 ($y = 5$). Substitute in the indeterminate expression, we get $x = 0.3333$ or $100x = 33.33$ lb. Take equation (1) again, and putting $y = 5$ and $x = 0.3333$ 1/3 we find $z = 2.5$; that is, limestone = $100z = 250$ lb. Our charge being now as follows, viz.: No. 1 = 100 lb., No. 2 = 33.33 lb., No. 3 = 500 lb., limestone = 250 lb., the proof consists, as before, in taking the percentages as shown by analyses on these weights.

| | $SiO_2$ | FeO | CaO | |
|---|---|---|---|---|
| Ore No. 1 (100 lb) | 40 | 10 | ... | lb. |
| Ore No. 2 (33 1/3 lb.) | 10 | 6.7 | ... | " |
| Ore No. 3 (500 lb.) | 50 | 150 | ... | " |
| Limestone (250 lb.) | 25 | ..... | 125 | " |
| | 125 | 166.7 | 125 | " |

Again the proof is perfect, for 125:166.7:125 = 3:4:3.

Thus, on the assumption that we use a portion of No. 1 ore, we find that up to a certain point we are restricted to the use of No. 3 only, but having passed that minimum we must use all three. Indeed there is but the one mix that excludes No. 2, viz.: 100 lb. of No. 1 and 425 of No. 3. Try to use less than 425 of No. 3 and we at once get irreconcilable results. This is not worth illustrating.

Finally to complete this discussion of the indeterminate, we may omit No. 1 ore, and recast our mixture, still getting an adjustment that will bring about the required slag. Leaving out No. 1 then, and assuming 100 lb. of No. 2 as our basis, keeping $100y$ for No. 3, and $100z$ for limestone, the problem passes out of the indeterminate class and becomes quite simple, i.e., with but a single solution. We have $SiO_2 = 30 + 10y + 10z$; $FeO = 20 + 30y$; $CaO = 50z$.

Equations are evidently as below:

$$30 + 10y + 10z = 50z \quad (SiO_2 \text{ and CaO equal})$$
$$4(30 + 10y + 10z) = 3(20 + 30y)$$
(Ratio of $SiO_2$ to FeO)

Divide through by 10, etc.:

$3 + y = 4z$ and $6 - 5y = -4z$ are the reduced forms. These give $y = 2.25$ and $z = 1.3125$. Or (multiplying by 100) charge is: Ore No. 1, 100 lb. Ore No. 2, 225 lb. Limestone, 131.25 lb.

*Proof.*

| | $SiO_2$ | FeO | CaO | |
|---|---|---|---|---|
| One No. 1, none. | | | | |
| Ore No. 2, 100 lb | 30 | 20 | ...... | lb. |
| Ore No. 3, 225 lb | 22.5 | 67.5 | ...... | " |
| Limestone, 131.25 lb | 13.125 | .... | 65.625 | " |
| | 65.625 | 87.5 | 65.625 | " |

The figures prove absolutely, i.e., as 3:4:3.

Practically, it is absurd to carry a slag calculation into second decimals of a pound. In demonstrating a *method*, however, it is well to carry accuracy far beyond any actual requirement.

Many changes might be rung on themes similar to these. The cases are not of a class likely to occur in every-day practice, but their discussion shows that there may be a variety of mixes all producing the same slag, and that there is no easier way of treating than the representative equation.

The attempt, in fact, to discuss most of such cases by "excess" would be, while hardly an impossible, certainly a tedious and confusing job.

Very notable is the fact that the equation method becomes *relatively easier* as the problem becomes more complex. Also, the fact that by this method the answer is final at the "first intention," and "readjustment" is never called for, is no small recommendation.

Finally, the proof is readily made, and clinches the figures past all cavil. It is to emphasize the latter point that we have carried out these proofs to an extent that might seem uncalled for.

Denver, Colorado.

## Refractometry

BY G. A. SHOOK

### II—Instruments

While a first-class spectrometer may be used for the determination of the refractive index of liquids, if it is provided with a hollow prism, considerable care must be taken in making an observation in order to obtain any degree of accuracy. This fact alone renders it unsuitable for commercial work.

The entire range of refractive indices, in the case of liquids is not greater than from $n_D = 1.3$ to $n_D = 1.7$, so that the spectrometer can be used for all sorts of research work. Where time is of any consideration, however, one of the commercial instruments should be used. Indeed practically all research work is now carried out with one or another of the well known refractometers.

In most all classes of work temperature control is an important factor and, therefore, a refractometer should be provided with suitable means for bringing the liquid, under investigation, up to any desired temperature and for maintaining it there for at least several minutes. Most of the instruments now in use are provided with water-jackets of some sort so that a stream of water may be circulated around the liquid. But the appliances that are provided by instrument makers for regulating the flow of water and for maintaining a constant temperature of the water are not always satisfactory. Of course, if the error introduced by a fluctuation of the temperature is not greater than is permissible, for the particular sort of work under consideration, then most any sort of a temperature regulating device may be used.

The choice of an instrument for measuring indices of refraction depends primarily upon two things: firstly the range of the instrument and secondly its sensitiveness.

Among other things which must then be considered are, the amount of the sample required to make an observation, the ease with which a reading may be made, etc.

Some instruments are provided with a direct-reading scale so that no computation nor even a table is necessary for the determination of $n_D$ while others are provided with arbitrary scales making it necessary to use a table if the index of refraction is desired.

Again white light may be used with some instruments, while with others monochromatic light must be used.

For butter and a number of oils the *Zeiss butyro-refractometer* is almost universally used. It has an arbitrary scale divided into 100 equal divisions and it covers a range of refractive indices from 1.4220 to 1.4895. It has an accuracy of about one unit in the fourth decimal place.

A similar instrument is the *Wollney milk-fat refractometer* which is designed for the determination of fat in milk. Its scale is also arbitrary and its range is from 1.3332 to 1.4220.

The *Abbé refractometer* is provided with a direct-reading scale and its range is from 1.3000 to 1.7000. It is used chiefly for edible fats, oils, lubricants, alkalis, linseed oil, petroleum, milk serum, jams, jellies, etc., etc., and it can be used for any substance whose index of refraction falls within its range. It has an accuracy of about two units in the fourth decimal place.

For dilute aqueous solutions the *Zeiss immersion refractometer* is especially suited. Its scale reads from —5 to 105 corresponding to a range of refractive indices of from 1.32539 to 1.36640 and its accuracy is about four units in the fifth decimal place.

For the determination of the dispersion as well as the refraction the *Pulfrich refractometer* is universally used. While it is more particularly a research instrument, it has been used to estimate alcohol and extract in beer and wine. It has an accuracy of about one unit in the fourth decimal place in the measurement of refraction and about two units in the fifth decimal place in the measurement of dispersion. It is made with the following ranges: 1.33 to 1.61 for liquids, 1.47 to 1.74 for solids and 1.64 to 1.88 for substances of exceptionally high refractive power. Its scale is graduated in circular degrees, but by means of a table the refractive index corresponding to any reading in degrees is readily determined.

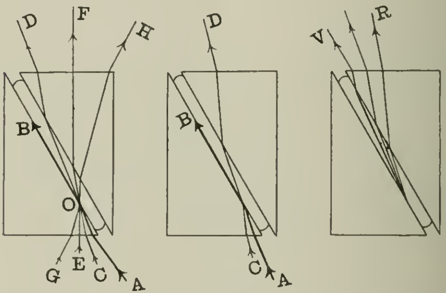

FIG. 1—BUTYRO-REFRACTOMETER DOUBLE PRISM

The Féry instrument has a range of 1.3300 to 1.6700 and is consequently suitable for oils or aqueous solutions. An accuracy of about one unit in the fourth decimal place may be easily obtained. The index of refraction is read directly from a scale attached to the instrument.

The values of the indices of refraction given above are all for sodium light.

The above named refractometers are the ones that are in most common use, although a number of others have been devised.

The theory of some of these instruments will now be taken up in detail.

### The Butyro Refractometer

The essential feature of this refractometer and also that of the Abbé is the so-called double prism. This consists of two similar prisms of highly refracting glass, Fig. 1, which are mounted in hollow cases. A stream of water, at any desired temperature, may be circulated around the prisms in order to maintain them at a constant temperature.

The liquid to be examined is placed between the hypotenuse faces of the prisms. The case containing the lower prism is hinged (at the lower edge) to the case containing the upper one so that it may be swung down to allow the introduction of the liquid.

A few drops only are required since the distance between the two adjoining interfaces is only about 0.015 cm.

The inner face of the lower prism is ground, so that every point upon it is a center from which light diverges. Let us now consider the first prism in Fig. 1.

We will suppose that it is filled with a liquid whose index of refraction is somewhat less than that of the prism. Light from beneath the lower face of the lower prism will pass through the point O in the direction OD, OF or OH, and pass out of the upper prism. But for some particular direction as AO, the light will just graze the surface of the liquid and will not be transmitted.

Any ray making a larger incident angle (with the normal to the liquid surface) than AO will evidently be totally reflected and, therefore, not enter the liquid. If, however, a ray such as COD makes an angle, with the normal, slightly smaller than the critical angle of incidence it will *just* be transmitted, so to speak. We will speak of this particular ray, hereafter, as the *limiting ray.*

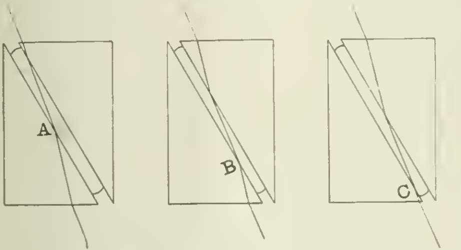

FIG. 2—LIMITING RAYS OF THE DOUBLE PRISM

All of the incident rays to the right of AO will be totally reflected, while all to the left, CO, EO, GO, etc., will be transmitted through the liquid and finally through the upper prism. The same is manifestly true for any point of the ground surface lying on a straight line drawn perpendicular to the plane of the paper through the point O.

Therefore, when one looks at the upper face of the double prism, he sees a light and a dark region separated by a sharp, straight boundary, provided the light is monochromatic.

Now if we consider any other point, along the ground surface of the inner face of the lower prism, such as A, B, or C, Fig. 2, we will have a similar system of rays. That is, parallel to the ray OD, which marks the limit of the light region for the point of divergence O, there will be a ray from the point A, one from B, and one from C, etc.

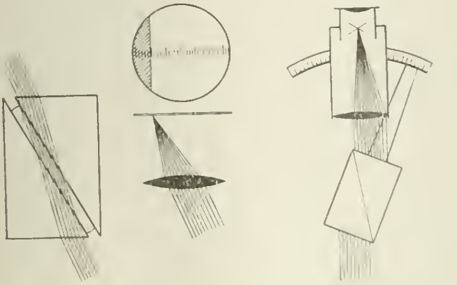

FIG. 3—OPTICAL SYSTEM OF THE BUTYRO REFRACTOMETER

If all of these parallel rays are brought to a focus by means of a lens they will produce an image of the boundary line, Fig. 3.

Moreover, since for every point on the ground surface, the critical angle of incidence must be the same, these limiting rays which just get through the liquid stratum must all be parallel and they must, therefore, all form one image.

The rays which emerge in any other direction, such as OF or OH, will produce by means of the lens images of light centers, as it were, that is to say they will produce a uniformly illuminated area.

In the Butyro-refractometer the upper prism is rigidly fastened to a frame which also supports, directly above the prism, a telescope. The telescope is focused for parallel rays and in the focal plane of its objective is placed a glass disk on which is engraved a scale. On looking through the telescope one sees the field of view divided into a light and a dark region as shown in Fig. 3. The position of the boundary line can be read directly from the superimposed scale.

For a liquid of smaller refractive power than the one just considered, the limiting ray CO will make a smaller incident angle and the emerging ray OD will consequently be more nearly perpendicular, as shown in the second diagram of Fig. 1. The dark portion of the field will in this case extend farther to the right, i.e., the border line will move across the scale.

In the Abbé instrument, instead of a micrometer scale in the telescope, the latter is provided with cross-wires and the double prism is rotated about an horizontal axis until the boundary line coincides with the cross-wires. An index hand or alidade attached to the prism system moves over a scale which is graduated to read the index of refraction, $n_D$, directly.

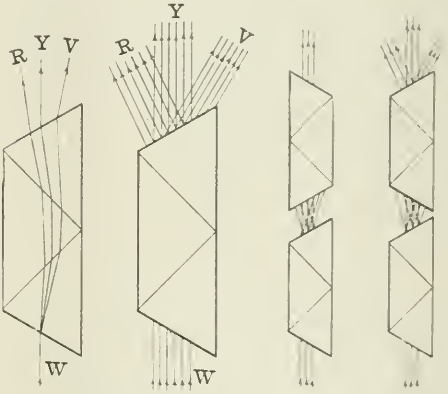

FIG. 4—AMICI PRISMS

Let us now suppose that the limiting ray OD, i.e., the one which produces the image of the boundary line is composed of white light instead of yellow light. As it enters the liquid stratum it will be dispersed into prismatic colors and the rays, corresponding to the various colors, that enter the upper prism, will thus be slightly divergent.

Consequently each ray will give rise to a different image of the boundary line for the position of the image of the boundary line on the engraved scale is determined solely by the direction of the emerging rays. That is, instead of the light and dark region being separated by a sharp colorless line, it will be separated by a colored and somewhat nebulous boundary.

It is readily seen that the upper face of the upper prism might, however, make such an angle with the hypotenuse face that the diverging rays leaving it would all be rendered parallel, in which case there would be but one image of the border line.

For simplicity, let us suppose that we have a violet, a yellow, and a red ray leaving the upper face of the double-prism as illustrated by the third diagram of Fig. 1. Since these three colored rays all make different angles with the prism face each will give rise to a separate image of the border line, but if they were all parallel they would all be brought to the same focus and consequently produce but one image.

Moreover, the direction of these parallel rays might be made the same as that of the yellow ray, in which case the reading of the instrument would be identical with the reading that would be obtained by using sodium light instead of white light or, in other words, the instrument would be "compensated for sodium light."

Evidently a refractometer can not be compensated for all substances. If it is compensated for a liquid of moderate dispersive power then for a liquid of high dispersive power it will not be quite compensated; that is, the rays leaving the upper face of the double prism will not be parallel and, therefore, a colored border line will result. Again it will more than compensate, so to speak, the dispersion of a liquid of low dispersive power.

The Butyro-refractometer prism is so constructed that the border line is achromatised for butter-fat. For a liquid having a dispersion smaller than butter, the red rays are deviated to the right of the yellow rays as shown in the third diagram of Fig. 1 and the violet rays are deviated to the left of the yellow rays, consequently the border line will be red.

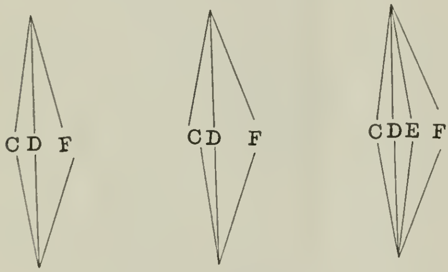

FIG. 5—PARTIAL AND COMPLETE COMPENSATION

For a liquid of greater dispersion the red rays are deviated to the left and the violet to the right of the yellow rays with the result that the border line is blue or violet.

*Therefore a blue border indicates a liquid of greater dispersion than that of butter, while a red border indicates a liquid of less dispersion than butter.*

It may happen, as was pointed out in the first article on refractometry, that two liquids will show the same refraction for, say, sodium light, but quite different mean dispersions and, therefore, the color of the border line should be noted in making an observation with this instrument. With the Abbé, the Zeiss, or the Pulfrich refractometer it is possible to measure the mean dispersion with accuracy, but such a measurement is not always of value.

The range of such an instrument depends manifestly upon the refracting power of the glass used in the construction of its double prism and it cannot, therefore, be altered in any way except by substituting a new prism having a different refracting power.

The only object of the lower prism is to hold the liquid, to be examined, and in one type of refractometer the lower prism is omitted and the upper prism is immersed into the liquid.

### The Abbé Refractometer

The essential difference between the Abbé and the Butyro-refractometer is in the method of compensating for sodium light and in the method of measuring the refraction.

To the double prism of the Abbé instrument is attached an alidade by means of which it may be rotated until the border line coincides with the cross-wires in the telescope, Fig. 3. The alidade moves over a scale on which is engraved the refractive indices.

Since the index of refraction may be read directly from this scale this instrument has some advantage over the one just described. Its chief advantage, however lies in its large range of refractive indices and in its compensating device by means of which the dispersion of practically any liquid may be compensated.

The Abbé compensator consists of two similar amici, or direct-vision, prisms. The amici prism is built of three triangular prisms and the middle prism has a different refractive power from the two outside ones, Fig. 4.

When a ray of white light enters either end of such a prism it is dispersed or spread out as shown. These dispersed rays upon entering the second prism are all bent back toward their original direction, but all to the same extent, i.e., they are not all parallel and, therefore, the dispersion is not entirely destroyed, although it is diminished. When these rays enter the last prism their dispersion is increased and when they enter the air it is further increased, but the general direction of the emerging rays is the same as the incident ray.

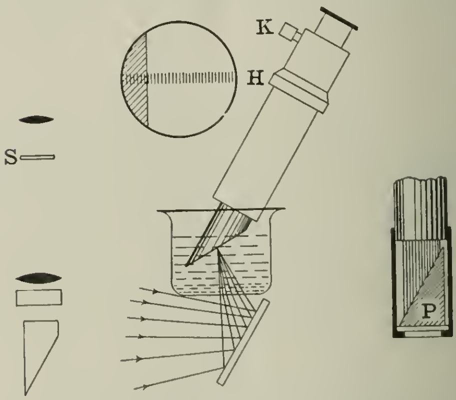

FIG. 6—ZEISS IMMERSION REFRACTOMETER

Evidently the prism can be so constructed that a particular emergency ray (say, the yellow one) will be parallel to the incident ray. Therefore, if a parallel beam of white light is incident on one face of such a direct-vision prism the emerging beam which is parallel to the incident beam will be yellow, while the beams emerging in other directions will have other colors as shown by the second diagram of Fig. 4.

It must be remembered that here we are always dealing with parallel rays of light and, therefore, we are concerned with the direction and not at all with the point, on the face of the prism, at which they emerge. At every point there are emerging rays of all colors and their direction is determined by their color. A diagram giving a more complete picture of such a system of rays would be too complicated to be comprehended.

Let us now consider what happens when parallel rays pass through two such prisms, Fig. 4. If the two prisms are oriented so that they oppose each other, as it were, the dispersion produced by the first will be completely annulled by the second so that a parallel beam passes through them without having its direction changed and without being dispersed.

If, however, they reinforce each other the second prism will augment the dispersion produced by the first. Therefore, by rotating one prism about the common axis of the two it is possible to produce any desired degree of dispersion from zero up to double the dispersion produced by either prism alone.

With respect to the spectrum, the center of rotation, so to speak, is always the D line, but, of course, a prism could be so made that the center of rotation would be any other line.

By means of such an arrangement it is readily seen that the dispersion produced by a liquid, inclosed in the double prism of the refractometer, may be completely annulled. Moreover, the direction of the compensated beam is the same as the direction of the yellow beam so that the reading of the instrument that obtains, when the light is compensated, is identical with the reading that would obtain if yellow light were substituted for white light.

The two amici prisms are mounted in the axis of the telescope between the telescope objective and the double prism and by means of a screw head they may be rotated simultaneously in opposite directions.

The angle through which the prisms must be turned, from the nil position, in order to compensate the dispersion of a given liquid is a measure of its *mean dispersion* and hence by means of the reading of the scale on the drum of the compensator the mean dispersion, $n_F - n_C$, may be computed. Tables are furnished with each instrument to facilitate this computation.

If, therefore, to an observer two oils are given which have the same $n_D$ but different values of $n_F - n_C$ he may distinguish them at once by means of such an instrument.

To be sure, by means of the Butyro-refractometer, one may determine the relative dispersion of oils by the color of the border line, but in such cases the indefiniteness of the border line makes an accurate measurement of the refraction impossible, while with the Abbé the border line may be made sharp and distinct for all dispersions.

It might so happen, of course, that the prisms could be rotated so that the partial dispersion $n_D - n_C$ would be compensated while the remainder of the mean dispersions, namely $n_F - n_D$, would not be compensated as illustrated diagrammatically in Fig. 5.

Again we might be able to compensate the region *F-D*, but not at the same time the region *D-C*, as shown.

In either case a very slight color would be given to the border line, but with most of the liquids with which we have to deal the partial dispersions are proportional to the mean dispersions so that if the mean dispersion of the compensator is made equal to the mean dispersion of the liquid the partial dispersions throughout the spectrum will be practically compensated as illustrated in the third diagram of Fig. 5.

### The Zeiss Immersion Refractometer

This instrument is not essentially different from the two just described.

The lower half of the double prism is omitted and the upper half is mounted in the end of a tube which contains a compensator and a telescope, Fig. 6. This tube is either hung on a rack or simply held in the hand. To make an observation it is only necessary to immerse the prism into the liquid whose index of refraction is desired.

The liquids to be examined are placed in small beakers and the latter are arranged in a water bath. This is simply a shallow metal tank provided with a glass bottom and an illuminating mirror so arranged that diffused sunlight may be reflected through the bottom of each beaker. The refractometer may then be dipped into one beaker after another.

In order to keep the beakers at a constant temperature the bath is filled with water at any desired temperature and the beakers are allowed to stand in it about ten minutes before any observations are made or the water is allowed to flow slowly through the tank.

The temperature of the bath is generally indicated by an ordinary thermometer immersed in the water, but in order to be sure that the solutions in the beakers have the same temperature as the surrounding water, it is necessary from time to time to measure the temperature of one or more of the solutions.

Whenever it is possible to provide a large quantity of the material to be tested, this instrument may be used efficiently as a large number of samples can be examined in a comparatively short time.

Its use is, however, limited to aqueous solutions or liquids having an index of refraction of about the magnitude of water.

The method of controlling the temperature of the substances to be tested is not the most satisfactory, however, since it is practically impossible to maintain a constant uniform temperature throughout such a large bath.

When only a small quantity of the sample can be obtained an auxiliary prism *P* is used. It is mounted in a short tube which can be secured to the refractometer tube, thus making a double prism. This arrangement is also used for volatile liquids.

There is a decided advantage, however, in using the single prism, for the border line is sharper than it is when the lower prism is used. Due to the fact that the border line is sharper a higher magnification may be used and consequently greater accuracy is possible.

The border line is made colorless by turning the collar *H* which in turn actuates the compensator. A fine adjustment is attached to the enclosed scale *S* and by means of a drum *K* the tenth part of a scale division may be easily read.

The ease with which this instrument can be manipulated and its extreme sensitiveness renders it invaluable for the investigation of solutions.

### The Pulfrich Refractometer

This instrument has no compensating device and, therefore, white light cannot be used.

It is provided with a Geissler hydrogen tube and sodium light is also used, so that the refractive index may be determined for the C, D, F, or G′ line and the dispersion may be determined for the interval D-C, F-D, G′-F, etc.

Light from a sodium flame, or any other source of monochromatic light, is rendered slightly convergent by means of a lens and thence passes into a right-angled prism under grazing incidence, Fig. 7.

The liquid to be tested is held in a short glass cylinder which is cemented to the top face of the prism.

Let us imagine that the three glass tubes in Fig. 7 are all filled with the same liquid and that, moreover, no light can pass into the prism except through the top face.

Since the index of refraction of the glass prism is much greater than that of the liquid to be tested, any ray, *AB*, passing along the interface will be bent into the glass at some point, *B*, and will pass out into the air along the path *BCD*.

For some other point, *F*, a ray entering the cell at grazing incidence will take the path *EFGH* and another ray the path *JKLM*, etc.

Therefore from the vertical face of the prism there will emerge a beam of parallel rays which have their origin from the rays that enter the top face of the prism under grazing incidence.

Any ray such as *PQ*, Fig. 8, which makes a small angle with the prism surface will, of course, pass into the prism and out again along some such paths as *QRS*. This emerging ray *RS* evidently makes a larger angle with the normal than the ray *CD*, which is due to the light entering the prism under grazing incidence.

Manifestly no light whatever will be transmitted in the direction *UV*, since *UV* makes a smaller angle with the normal than the ray *CD* and would consequently have to arise from a ray having the direction *TQ*, but no light can pass along the path *TQ*, since none enters the prism except through the top face.

Therefore, if an observer were to examine the vertical face of the prism by means of a telescope, focused for parallel rays, he would observe that the field of view were divided into a light and a dark region by a sharp boundary line as shown in Fig. 8.

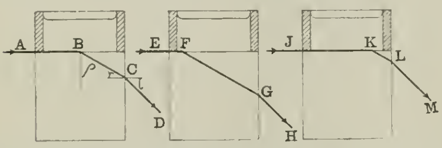

FIG. 7—TOTALLY REFLECTING PRISM OF THE PULFRICH REFRACTOMETER

The angle *i*, Fig. 7, depends clearly upon the refractive index of the glass and of the liquid. For a given glass prism, therefore, *i* will depend solely upon the refractive index of the liquid contained in the glass tube.

Now suppose that the light were passing in the direction *DC*, then if the index (referred to air) for glass is *N* it follows at once that

$$N = \frac{\sin i}{\sin r}$$

Moreover, the index of the liquid (referred to air) is

$$n = \frac{\sin \varphi}{\sin 90} \times N = \sin (90 - r) \times N$$

$$= \cos r \times N = \sqrt{N^2 - N^2 \sin^2 r}$$

But

$$\sin^2 r = \frac{\sin^2 i}{N^2}$$

hence

$$n = \sqrt{N^2 - \sin^2 i}$$

Knowing the index for the glass, *N*, the index of any liquid, *n*, may be readily computed if the angle *i* is known. Tables are furnished with each instrument so that the index of refraction, *n*, may be readily obtained from the value of *i* (in degrees).

In reality the telescope is at right angles to the emerging beam and the beam is reflected into it by means of a 45 deg. prism. The telescope is attached to an arm which rotates about an horizontal axis which lies in the plane of the vertical face of the prism. This arm is provided with an index which moves over a scale so that *i* may be read in degrees. To make an observation it is only necessary to rotate the arm, carrying the telescope, until the cross-wires of the latter coincide with the boundary line between the bright and dark region.

The scale is also provided with a micrometer attachment so that small differences in *i* can be readily measured to within one-tenth of a second. Very often one is concerned only with small differences in the refractive index, such as may be caused by small changes in temperature, in which case the micrometer is extremely convenient.

When it is desired to measure the difference in the refractive powers of two liquids, for example, water and a weak solution of alcohol, a special form of cell is sometimes used. It is provided with a black glass partition and when the cell is in position the partition is perpendicular to both prism faces.

The two liquids to be examined are placed in the two separate compartments. Two border lines will now be observed instead of one and the angular difference between them can be easily and accurately measured by means of the micrometer. All errors due to temperature differences are thus avoided.

The temperature of the liquid is controlled by means of a hollow casing surrounding three sides of the prism, through which a stream of water at any desired temperature or steam may be passed. The liquid may also be heated inside the glass cylinder directly by means of a cylindrical heating vessel, of special construction, which dips into the liquid, *W*, Fig. 8.

The water or steam from the casing of the prism passes through the heating vessel and comes in direct contact with the bottom plate of the same. The vessel can be lowered until it is less than a millimeter from the prism surface so that there is practically no uncertainty whatever as to the temperature of the liquid.

### The Féry Refractometer

This instrument has several decided advantages over those just described. The index of refraction of any transparent liquid may be read directly with an accuracy of about one unit in the fourth decimal place and the scale extends with uniform accuracy from 1.3300 to 1.6700. Sodium light is used so that no compensating device is necessary. No auxiliary heating apparatus is required, since the temperature control is an integral part of the apparatus. Moreover, it is only necessary to have 1 cc to 2 cc of the liquid to be tested.

A diagrammatic view of this refractometer is shown in Fig. 9. The essential parts of the apparatus are: a collimator, *C*, of special construction; a telescope, *T* (in line with the collimator); a double cell, *S*, and a heating device not shown.

The outer cell is entirely of metal with the exception of the two larger sides which are plano-convex lenses as shown. The inner widge-shaped cell is made of glass and into this cell the liquid to be examined is introduced. The space between the inner and outer cell is filled with water which may be heated to any desired temperature by means of a thermo-syphon which is actuated by a small lamp attached to the double cell. A copper tube of small diameter is brazed to the metal chimney of the lamp and the two ends of this tube are inserted into one end of the outer cell so that an active circulation of the water is produced.

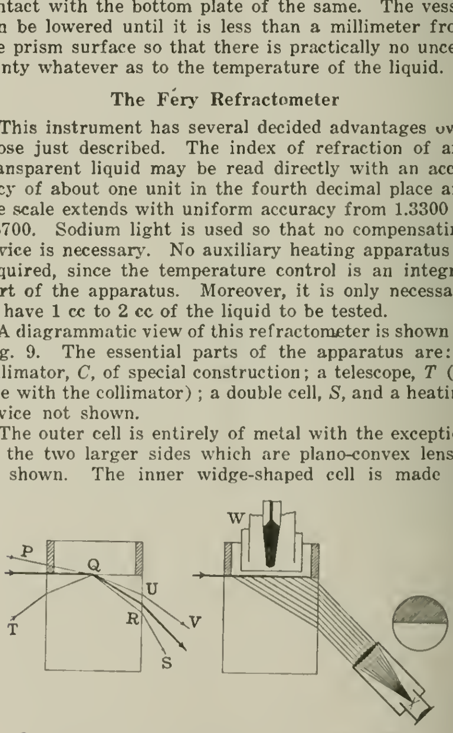

FIG. 8—OPTICAL SYSTEM OF THE PULFRICH REFRACTOMETER

By means of a rack and pinion the double cell may be moved perpendicular to the optical axis of the instrument. When the telescope is properly adjusted, the image of a fine wire in the focus of the collimating lens coincides with the cross-wires of the telescope.

Now when the cell is symmetrical with respect to the axis of the collimator and telescope, the prism of liquid deflects the beam from the collimator out of its path so that the wire image no longer coincidees with the cross-wires of the telescope.

By moving the double cell, however, the wire image can be made to coincide with the telescope cross-wires and the movement necessary to effect this condition is a measure of the index of the liquid under consideration.

The action of this double cell may be readily understood by means of Fig. 10. If the inner cell were not present then the beam from the collimator would pass directly through the two lenses as shown by the first diagram. If now a wedge of any transparent substance, for instance, glass, were placed in the cell, the beam would be deflected and would not pass directly through the telescope as shown by the second diagram. The beam can, however, be brought back to its original direction by moving the cell to one side as shown by the third diagram.

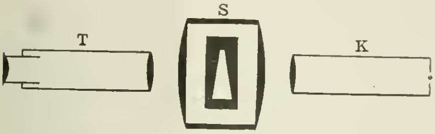

FIG. 9—FÉRY REFRACTOMETER

For a prism set at minimum deviation, the index of refraction, in terms of the prism angle, $A$, and the deviation angle, $D$, is given by the well-known formula

$$n = \frac{\sin\left(\frac{A+D}{2}\right)}{\sin\frac{A}{2}}$$

In this case $A$ and $B$ are both small so that the sign is practically equal to the angle when the latter is measured in radians.

Therefore,

$$n = \frac{A+D}{A}$$

or

$$D = A\ (n - 1)$$

That is, the index, $n$, is directly proportional to the deviation $D$. The lenses of the outer cell constitute prisms of variable angle.

At the pole of the lens this angle is evidently zero, but at the periphery it has a small but finite value. Moreover, this angle varies directly with the distance from the pole of the lens. A little consideration will show that the deviation, $D$, is directly proportional to the distance that cell must be moved in order to compensate for the deviation produced by the liquid prism.

The divisions of the scale, which is attached to the double cell, are therefore equal; moreover, each division represents the same increment in $n$. By moving the inner cell (in the direction of its length) with respect to the outer cell the direction of the emergent beam is manifestly altered and consequently the range of the instrument is changed. It is by this simple expedient that the range of the instrument is increased without diminishing its accuracy.

For one position of the inner cell it reads from 1.3300 to 1.5326, and this range is suitable for most of the liquids of industrial interest. By shifting the cell to another position the range of the scale is extended by 0.14 so that it works between 1.4700 and 1.6726.

It is thus seen that the type of instrument which is best suited to a particular laboratory depends entirely upon the class of substances to be analyzed and upon the conditions under which the analysis is to be carried out.

* * *

If the samples to be tested differ widely in their refractive powers then unless more than one instrument can be purchased the choice lies between the Abbé and the Féry refractometers.

If, furthermore, only a drop or two of the sample can be obtained, which is seldom the case, the Abbé instrument would be more applicable than the Féry.

The Féry instrument, however, is more accurate and more self-contained since its heating control forms part of the apparatus. For the exclusive examination of solutions the Zeiss instrument is preferable, provided a comparatively large quantity of the sample is available.

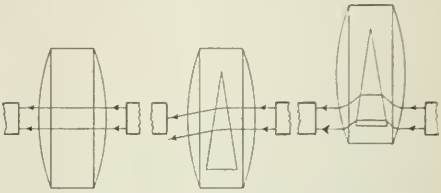

FIG. 10—DOUBLE BELL OF THE FÉRY REFRACTOMETER

If it is desired to measure the dispersion as well as the refraction, then either the Abbé, the Zeiss or the Pulfrich instrument may be used.

The Pulfrich is undoubtedly more accurate for dispersive measurements than the Abbé or Zeiss, but, on the other hand, a measurement of the dispersion is more easily made by means of either of these two instruments.

For research work the Pulfrich refractometer is probably the best all-round instrument.

University of Michigan,

---

**Direct shipments** of freight into Mexico over the International bridge between Nuevo Laredo, Mexico, and Laredo, Texas, have been resumed.

**The domestic iron-ore output in 1913** was the largest in the history of the country, according to figures issued by the Geological Survey, amounting to 61,980,437 long tones, an increase of over six million tons over the production of 1912. Minnesota produced over five-eighths of the total. The Mesabi range produced nearly 70 per cent of the entire Lake Superior output, and nearly 59 per cent of the production of the country.

**Stratton's Independence, Ltd.**, at Cripple Creek, produced 1176 tons of mine ore averaging about $16 per ton, and the mill treated 11,700 tons of low-grade mine and dump ore, during the month of June. The net working profit to the company from both mine and mill operations was $14,420.

**The potentials of different minerals** when employed as electrodes in different solutions is one of the subjects discussed in *Bulletin* 548 of the U. S. Geological Survey, entitled Electric Activity in Ore Deposits. Although the object of the investigation is primarily related to mining and geology, some of the experimental work is of interest to electrometallurgists. The electric conductivity of minerals, measurements of potential assumed by certain minerals, and electromotive behavior of soluble sulphides are some of the subjects discussed.

# Cyanide Practice in the Porcupine District, Ontario, Canada—II

BY H. C. PARMELEE

In a previous article[1] reference was made to the fact that, of the four principal cyanide mills in the Porcupine district, no two have adopted exactly the same method of ore treatment, and that in spite of the general similarity of the ores there is marked diversity in the methods. In order to bring this point clearly to mind, a comparison has been made in Table I, showing the different steps and means of accomplishing them.

TABLE I—COMPARISON OF METHODS OF PROCEDURE ADOPTED AT PORCUPINE CYANIDE MILLS

| Mill | Crushing | In | Classifiers | Amalgamation | Concentration | Cyanidation | Filtration | Precipitation | Refining |
|---|---|---|---|---|---|---|---|---|---|
| Hollinger...... | Stamps and tube mills | Solution | Dorr | None | Deisters | Continuous decantation of slime. Agitation of concentrate | Moore vacuum | Zinc dust | Blast furnace Cupellation |
| Porcupine-Crown .... | Stamps and tube mills | Solution | Dorr | Following tube mills | None | All-sliming. Continuous decantation | None | Zinc dust | Rockwell furnace |
| McIntyre... | Rolls, Hardinge ball mills and tube mill | Solution | Dorr | None | None | All-sliming. Continuous decantation | None | Zinc dust | Crucible furnace |
| Dome........ | Stamps and tube mills | Water | Colbath | Following tube mills | None | Leaching of sand. Agitation of slime | Merrill press | Zinc dust | Blast furnace. Cupellation |

### Continuous Decantation at the Porcupine Crown Mill

One of the most interesting mills in the district is that of the Porcupine Crown Mines, Ltd., at Timmins. The principal feature of the plant, and the one that lends simplicity to the metallurgical scheme, is continuous counter-current decantation for the displacement and recovery of valuable solution from the impoverished ore-slime. The diagram in Fig. 1 gives an outline of the treatment, and shows also the more important data relative to continuous decantation.

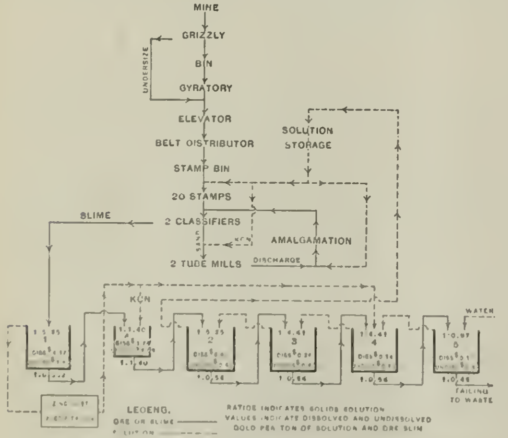

FIG. 1—DIAGRAM OF ORE TREATMENT AT PORCUPINE CROWN MILL

The ore is mainly quartz containing free gold. There is less schist than at some of the other properties, and only 1 per cent of pyrite, as compared with from 5 to 10 per cent elsewhere in the district. The value of the mill feed ranges from $15 to $30 per ton. Some of the gold is coarse and readily amalgamable; the balance is easily soluble in a comparatively weak cyanide solution. The ground ore is granular and settles rapidly, so that on the whole the metallurgical problem is simple and the process well adapted to the requirements and conditions.

There is nothing particularly new in the preparation of the ore for cyaniding. It is screened through a grizzly, 1½-in. spaces, and the oversize is crushed in a gyratory and combined with the grizzly undersize. The whole is then elevated and distributed to the stamp bins. Challenge feeders deliver the ore to twenty 1050-lb. stamps, arranged in batteries of ten each, with separate cam shafts for each group of five. A 40-hp. motor with silent-chain drive serves each battery.

### Crushing and Grinding in Solution

The ore is stamped in mill solution returned from the continuous decantation system, four tons of solution being used per ton of ore. The stamp discharge flows to Dorr classifiers which deliver the coarse portion to tube mills for regrinding. The tube mill product is elevated to amalgamating plates and returned to the classifiers. Thus tube milling and amalgamation are performed in a closed circuit, and there is no opportunity for escape of the pulp until coarse gold has been amalgamated or ground fine enough to escape with the slime.

El Oro lining is used in the tube mills, but the Globe liner, previously mentioned in the description of the Hollinger mill,[2] is to be given a trial. The pebble load is maintained at 0.6 the volume of the tubes. The mill solution used in the tube mills is first strengthened with cyanide, and the flow regulated to give 38 per cent moisture in the pulp. The latter is then suitably diluted with mill solution before amalgamation. Preliminary experiments in grinding for cyanidation showed that the critical degree of fineness for this ore was about 150-mesh. In current mill practice 88 to 90 per cent of the ore is finer than 150-mesh and 75 per cent finer than 200-mesh.

The well known difficulty of maintaining amalgamating plates in good condition when using cyanide solution is experienced at this mill, but the plates serve their purpose of catching coarse gold, and effect about one-third of the total recovery. The amalgam is hard and must be scraped from the plates, care being taken not to cut too deep and injure the amalgamating surface.

### Continuous Counter-Current Decantation

The overflow of the classifiers, consisting of 1 part of solids and 5.25 parts solution, passes to the continuous decantation plant which comprises five Dorr thickeners, 30 ft. by 12 ft., and two Dorr agitators, 16 ft. by 16 ft., together with the necessary complement of diaphragm pumps for transfer of pulp. This machinery is housed in the long structure shown at the left in Fig. 2, the crushing, grinding and amalgamating equipment being placed in the higher part at the right. An interior view of the continuous decantation plant is given in Fig. 3, looking from left to right through the building shown in Fig. 2. The relation of the thickeners and agitators is shown diagrammatically in Fig. 1, and the counter-current flow of solids and solution, and displacement of the latter will be readily understood by reference thereto. There is no filter in this plant.

---

[1] This Journal, September, 1914, p. 567.

[2] Ibid.

Examination of the figures given in the flow sheet will show uniform reduction in value of the solution throughout the line of thickeners, ending with a value of only ten cents per ton in No. 5. As the discharge from this thickener contains only 0.43 ton of solution per ton of ore, the loss of dissolved gold is but 4.3 cents per ton of ore, which is a remarkably satisfactory result and one that compares favorably with displacement by filtration. Recyaniding tests on the washed tailing show that only an inconsiderable quantity of gold can be extracted without finer grinding. The only water entering the system is used to dilute and wash the pulp in No. 5 thickener and counterbalance the loss of solution in the tailing.

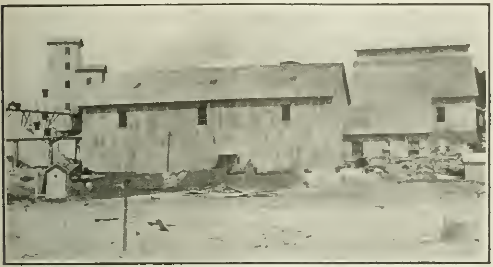

FIG. 2—PORCUPINE CROWN MILL

The physical arrangement of the thickeners is such that overflowing solutions pass by gravity from No. 5 to No. 2. A suggestion of the arrangement can be gathered from Fig. 3, wherein the upper part of thickener No. 5 is seen in the central background, and No. 4 at a lower level in the left center. No. 3, not visible, is at a still lower level in line with Nos. 5 and 4. The rim of No. 2 is barely seen in the right foreground, with a launder leading to it from the agitator which is in the right center. Thickener No. 1 is behind the agitator. Fig. 4 shows the manner of supporting the thickeners on concrete piers, providing for the proper elevation of the vats and permitting ready access to the discharge pipes.

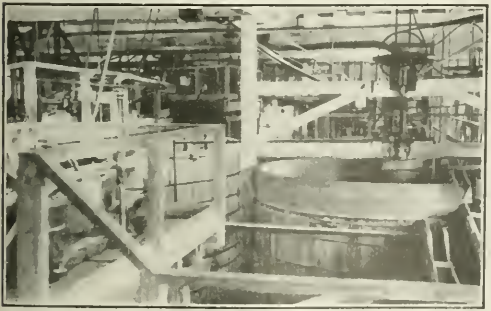

FIG. 3—CONTINUOUS DECANTATION PLANT, PORCUPINE CROWN MILL

**Thickened Pulp Transferred by Diaphragm Pumps**

Diaphragm pumps are used for the transfer of thick pulp throughout the system. These are installed in duplicate at each point of transfer, one being held in reserve. They are ordinary contractor's pumps, costing about $35 each. As originally purchased they are operated by cranks, but give better satisfaction when driven from eccentrics. The change is easily made and results in less lost motion and longer life of diaphragms. As installed at this mill the pumps have two speeds and three lengths of stroke whereby the volume of pulp handled can be varied to suit conditions in the thickeners and possible changes in mill tonnage.

In the design of the continuous decantation plant, four square feet of settling area was provided per ton of dry slime, based on the treatment of 180 tons per day. Only one agitator was originally installed, but a second has been added, as it was found that dissolution of gold continued through the line of thickeners, indicating insufficient agitation. Although but one agitator is shown in the diagram, there are two connected in series. One-third of the cyanide is added to the barren solution that dilutes the pulp in the agitators, the balance being added at the tube mills. Lime is mixed with barren solution in a small barrel, and the resulting emulsion can be conducted through launders to all thickeners and agitators, so that alkalinity can be maintained as desired.

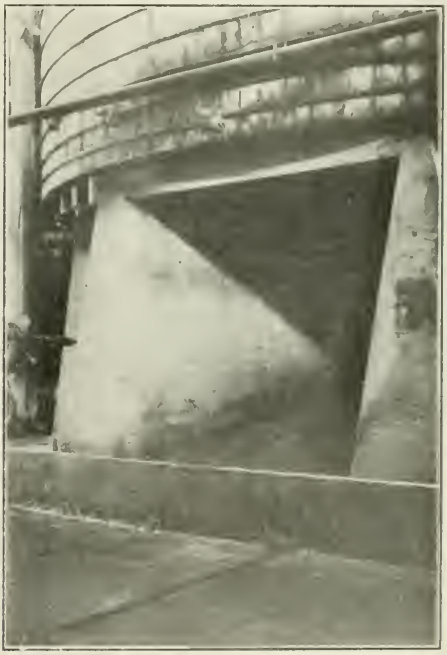

FIG. 4—CONCRETE FOUNDATION FOR THICKENERS

The ratios and values given in Fig. 1 represent conditions in the month of April, 1914. The strength of solution is 1.25 lb. KCN per ton; protective alkalinity is 1 lb. per ton. Chemical consumption per ton of ore milled is 0.75 lb. KCN and 3.5 lb. CaO. Zinc dust consumption is $^1/_6$ lb. per ton of solution precipitated. About four tons of solution is precipitated per ton of ore treated. Value of the head solution in April was

$2.32; tailing solution, $0.03. Percentage recovery is between 96 and 97, and milling costs range from $1.20 to $1.25, exclusive of charges for administration, depreciation, etc.

### Precipitation and Refining

The overflow from thickener No. 1 is the solution precipitated. This solution is first clarified through gravity filter leaves and then pumped to a Merrill press by an Aldrich triplex pump, at the suction of which zinc dust emulsion is introduced. A clean-up is made twice monthly. The precipitate is treated with acid, pumped to a Perrin press and washed therein. The press cake is then partly dried and mixed with fluxes in the following quantities per 100 lb. of precipitate: borax glass, 11.5 lb.; soda, 5.7 lb.; silica, 3 lb. This mixture is then briqueted, dried and melted in an oil-fired Rockwell furnace, yielding bullion about 850 total fineness, of which 90 to 100 is silver and the balance gold.

FIG. 5—ORE-TREATMENT DIAGRAM, DOME MILL

All of the floors in this mill are of cement, draining to a concrete sump at the foot of the mill. A hint of this construction is given in Fig. 4, showing the floor beneath the thickeners. This is a commendable feature in mill construction that contributes to cleanliness and prevents loss of valuable solution through accidental overflows from any of the machines. A centrifugal pump placed in the sump returns the accumulation to the tubemill-classifier circuit.

### The Dome Mill

Radical changes have recently been made at the mill of the Dome Mines Co., Ltd., at South Porcupine. Not only has the capacity of the mill been doubled and the mechanical method of preparing and handling the ore been changed, but the metallurgical scheme also has been altered by the abandonment of primary amalgamation following the stamps, and the introduction of sand-slime separation, with leaching of the sand product. The slime is cyanided by agitation and filter-pressing as heretofore. The equipment and new scheme of treatment are shown diagrammatically in Fig. 5. Some data on former mill operation have been published in this journal.[3]

In explanation of the changes that have been made, it may be said that they have been due in large measure to the way in which the mine has developed. When the original mill was designed the mine had not been opened extensively and the ore was high-grade. Furthermore, there was urgent demand for a mill on the part of the company, and the plant had to be designed on rather meager data regarding future ore supply. With the development of the mine, larger bodies of low-grade ore were disclosed,[4] and the problem became one of handling a large tonnage of low-grade ore most economically. Tests made in the interim yielded information that could not have been gained originally, and suggested the changes in practice that have since been made. The remodeled mill will handle double the tonnage of the former, and an effort will be made to treat about 1000 tons of ore daily. There will be little more cost for labor, and grinding cost will be reduced as half the ore will be leached instead of being finely ground and agitated. The general effect of the change, therefore, is to increase tonnage and reduce operating cost.

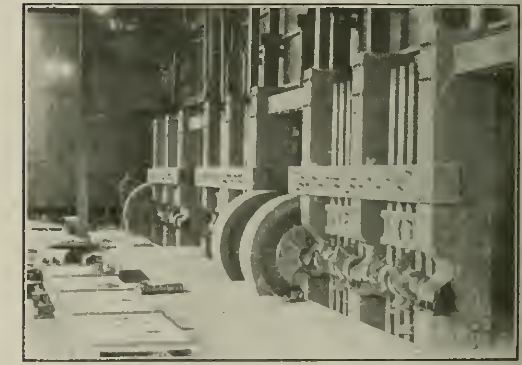

FIG. 6—NEW STAMPS, DOME MILL

### Jaw-Breakers Supersede Gyratories

For coarse breaking gyratories have been displaced by Farrell jaw crushers with water-cooled bearings. The objection to the gyratories was the high cost of repairs due to excessive wear in the bottom bearings. It appears that fine schist dust gradually worked its way into these bearings and gave considerable trouble.

The crushed ore is elevated by an inclined belt-conveyor to the mill bins, above which provision has been made for screening out the fine portion and by-passing it to the tube mills, thus relieving the stamps of an unnecessary burden.

The new addition of forty stamps has been placed back-to-back with the original forty. A view of part of the new installation is shown in Fig. 6. The battery foundations are of concrete, recessed along the sides to receive 8 in. by 8 in. timbers through which the 1½-in. mortar bolts pass. Both mortar and post bolts are removable without difficulty. The mortars are fitted with manganese-steel liners, and the shoes and dies are of forged chrome steel.

---

[3] The Dome Mill, D. L. H. Forbes, this journal, May, 1914, p. 349

[4] In the company's annual report for 1913 it is stated that development work has disclosed a large tonnage of ore assaying from $3.50 to $5 per ton.

### Ore Crushed in Water and Amalgamated

The Dome is the only one of the large Porcupine mills to adopt crushing in water. It is also the only one in which amalgamation is relied upon for the major part of the recovery, amounting in this instance to from 60 to 70 per cent. Of this quantity, about 90 per cent is recovered on the tube mill plates and 10 per cent on the plates following hydraulic classification.

With the adoption of coarse crushing in the batteries, the practice of amalgamating the stamp discharge has been discontinued. Stamp duty has increased from 6½ tons per 24 hours with 18-mesh screen to 14 tons with ton-cap screen of about ½-in. aperture. The battery discharge flows to Dorr classifiers which deliver the coarse portion to tube mills. Formerly, when all-sliming was practiced, the tube mill discharge was returned to the classifier, and only the slimy overflow of the latter was considered a finished product of the grinding department. Now the tube mill discharge is combined with the classifier overflow and much less fine grinding is done than formerly. From 40 to 50 per cent of the pulp is finer than 200-mesh; all will pass 60-mesh.

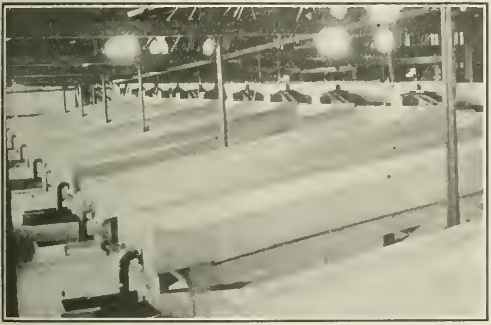

FIG. 7—AMALGAMATING PLATES, DOME MILL

The El Oro lining has been adopted in these tube mills. Silex linings have been tried and found less satisfactory. The former last about nine months as against seven months for the latter. Pebble consumption is 4½ lb. per ton of ore ground.

Twenty-four amalgamating plates, 54 in. by 144 in., are placed on the upper floor of the new addition to the mill, being arranged in two rows of twelve each on either side of a central launder. Fig. 7 gives a view of part of the plates and shows the pulp-distributing system.

### Hydraulic Classification of Sand and Slime

From the plates the pulp flows to a series of Merrill hydraulic cones where a separation of sand and slime is made, approximately in equal parts. The sandy portion is then treated in Merrill concentrating cones, where the pyritic concentrate, that constitutes from 5 to 8 per cent of the ore, is separated. This is first amalgamated and then returned to the classifiers and tube mills. By this method of handling the concentrate, it is not separated for special treatment as at the Hollinger, but reground until it is fine enough to escape from the classifiers with the slime.

The sand separated from the concentrating cones flows through Butters and Mein distributers to leaching vats on the floor below the plates. A view of the vat room is given in Fig. 8. These vats are 40 ft. by 8½ ft., with the usual filter-bottom. The surface of the bottom slopes from two opposite sides of the vat to a median line, at each end of which is a gate for discharge of the leached sand. A complete cycle of filling, leaching, washing and discharging requires about 6 days time, of which 5 days is required for leaching. The ore column is 7½ ft. high and the leaching rate is 2½ to 3 inches.

### Slime Agitated and Filter-Pressed

Slime from the hydraulic cones is first thickened in Dorr continuous thickeners. Cyanide is added and the pulp is agitated for fourteen hours in four 8-ft. by 40-ft. Pachuca tanks connected in series. Air is used at 20 lb. pressure. The agitated pulp is collected in a storage tank where it is mechanically agitated to prevent settlement, and from which charges are drawn intermittently for filtration through Merrill presses. In view of the well-known adaptability of the Merrill press to the leaching of granular slime *in situ*, it is possible that the Pachuca agitators might be cut out and the slime dewatered and leached in the presses.

Pregnant solution from the presses and the leaching vats is precipitated with zinc dust in the usual manner. Consumption of zinc dust is one-fifth to one-sixth of a pound per ton of solution. The refining process is similar to that used at the Hollinger, except that the precipitate is given an acid treatment before it is fluxed and smelted. The resulting base bullion is cupelled. Amalgam is retorted and refined in the usual manner. The final bullion is about 990 fine, of which 100 is silver.

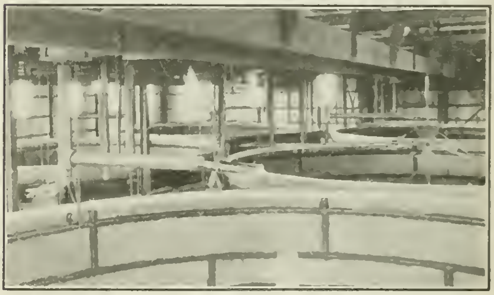

FIG. 8—LEACHING VATS, DOME MILL

The new scheme of treatment has not been in effect long enough to secure average data on operation. In 1913, under the old process of all-sliming, the average value of the ore treated was $8.77 per ton; recovery 94.51 per cent; percentage of total recovery by amalgamation, 60.7, and by cyanidation, 39.3. Average cost of milling was $1.44 per ton, distributed as follows: stamping, tube milling and amalgamation, $0.86; thickening, cyaniding and precipitating, $0.50; refining, $0.08. Coarse breaking and conveying to the mill cost $0.25 per ton, but this item is expected to be materially reduced under the new scheme.

### The McIntyre Mill

Important changes and increase of capacity have been contemplated at the 150-ton mill of the McIntyre-Porcupine Mines, Ltd., at Schumacher. Filtration in a Burt revolving filter is to be superseded by continuous decantation. Consequently little will be said about current operations as they are likely to be changed materially. There are, however, a number of interesting features about this plant that merit consideration.

The ore treated at the McIntyre differs from that at the other mills in the quantity of schist contained. At times this material constitutes as much as three-fourths of the mill feed. Pyrite exists in varying quantities, from 5 per cent to 10 per cent. Some of the pyrite is nearly barren, but much of it carries gold which is readily soluble when finely ground. In fact, when the mill is running on the more heavily mineralized ore, 80 per cent of the total gold extraction takes place in the tube mill-classifier circuit. This action is not so marked when treating ore that is mainly quartz, and subsequent agitation then becomes of greater importance. No trouble is experienced from foul solutions, and aside from being slightly acid, the ore contains no cyanicides.

### Rolls and Hardinge Ball-Mills for Grinding

The first distinguishing feature of McIntyre practice is the use of rolls and Hardinge ball-mills for the intermediate crushing performed at the other plants by stamps. A tube mill in closed circuit with a classifier completes the fine-grinding system. This combination of crushing and grinding apparatus offers some advantages in simplicity, both in installation and operation, as compared with stamps. The cost for supplies at the McIntyre amounts to only 7 cents per ton for steel consumed in the Hardinge ball-mills, including balls and the metal discarded in worn liners. Crusher and roll supplies cost 1 cent per ton. In addition to the simplicity of the roll-ball mill combination, there is also a certain advantage in the absence of noise which characterizes a stamp mill. It has been observed before that "noise costs money" in a variety of ways, and that, other things being equal, the quiet machine is preferable to the noisy one.

Coarse breaking at the McIntyre is performed with crushers of the Blake type, set to deliver a 1-in. product. Rolls reduce this to ¼ in., at which size the ore is fed to the Hardinge ball mill and ground in mill solution. Carborundum blocks are successfully used to prevent corrugation of the roll shells, which, after having been in service for fifteen months, had an estimated further life of eight to ten months.

### Tube Milling in Closed Circuit

The ball mill feed is equal parts of ore and solution. Balls vary in size from 5 in. to 3 in. in diameter, and both liners and balls are of chrome steel. The following table gives a screen analysis of the average discharge of the ball mill, grinding 150 tons per day and consuming 33 hp.

| Mesh | Per cent |
|---|---|
| + 20 | 5.0 |
| + 40 | 22.6 |
| + 60 | 9.6 |
| + 100 | 15.0 |
| + 200 | 13.4 |
| − 200 | 34.4 |

This product goes to a Colbath screw classifier, where it is diluted with mill solution in the ratio of 3 or 3½ to 1. The slime overflows to Dorr thickeners, the balance going to a tube mill and returning to the classifier. Little dissolution of gold takes place in the Hardinge mill, where approximately 40 per cent of slime is made, and subsequent agitation must be relied upon to extract the gold from this portion of the ore. Approximately 60 per cent, however, gets repeated agitation in the classifier and tube mill, where the major part of the metal is dissolved. Cyanide is added at the tube mill, where the consumption is heaviest. The tube mill pulp contains 35 per cent moisture.

### Continuous Decantation of Slime

The overflow from the classifier contains 3 per cent to 4 per cent solids coarser than 100-mesh, and 10 per cent to 12 per cent coarser than 200-mesh. The balance is finer than 200. The plus 100-mesh portion is almost barren and consists of flaky schist that is difficult to grind. Formerly the slime was treated by continuous decantation in two steps with intermediate agitation, and the pulp was finally filtered in a Burt revolving filter. The overflow of the primary thickener was precipitated, and the solution from the filter was returned as mill solution.

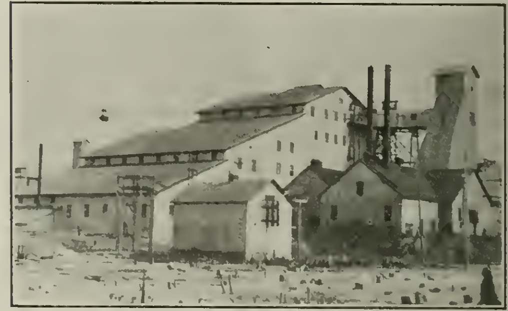

FIG. 9—MCINTYRE PORCUPINE MILL

The proposed change in the system will eliminate the filter altogether and use continuous counter-current decantation as described above in connection with the Porcupine Crown mill.

Despite the presence of much schist in the ore, settlement is reasonably rapid as shown by the fact that 150 tons per day has been handled by a Dorr thickener 30 ft. in diameter and 12 ft. deep.

Zinc dust precipitation has been in use at this mill, precipitating 3½ tons of $2.50 to $3 solution per ton of ore. The precipitate is given an acid treatment, then fluxed with soda, borax, nitre and silica, and melted. The resulting bullion is from 820 to 860 fine. Extraction has been about 95 per cent. Milling cost has averaged from $1.30 to $1.35 per ton, of which $0.50 was for supplies, $0.46 for labor, $0.30 for power, and $0.04 for assaying.

A detailed statement of cost and supplies is given in the following table:

| Supplies | Cost per ton |
|---|---|
| Cyanide | $0.080 |
| Zinc | .075 |
| Lime | .012 |
| Crushers and rolls | .010 |
| Hardinge balls and liners | .071 |
| Tube mill (El Oro liner and pebbles) | .035 |
| Clarifying gold solution | .012 |
| Belting, oil and miscellaneous | .054 |
| Filtering | .033 |
| Pumping and elevating | .027 |
| General repair parts | .028 |
| Refining | .063 |
| | $0.500 |

The use of continuous decantation without filters was first proved successful in the Porcupine district at the Porcupine Crown mill. Since then it has been adopted by the McIntyre and Vipond, and the Hollinger is to add a 300-ton unit on this basis. The Tough-Oakes in the Kirkland Lake district is also considering the addition of such a plant to its present stamp-amalgamation mill. On the whole the system seems to be meeting the requirements in this district and is likely to be more extensively adopted.

For courtesies extended while in the Porcupine district we wish to express our thanks to local engineers generally, and particularly to Messrs. F. C. Languth and W. F. Battersby, of the Dome; M. W. Summerhayes, of the Porcupine Crown, and R. J. Ennis and A. Dorfman, of the McIntyre.

# Chicago Convention of American Institute of Metals

At the opening session of the annual convention of the American Institute of Metals, which was held in Chicago on Sept. 8 jointly with the American Foundrymen's Association, Mr. G. H. Clamer, the president, gave a short sketch of the rise of the society. He said that the Institute was an offshoot of the American Foundrymen's Association. It was organized in Philadelphia in 1907 as the American Brass Founders' Association. Four years later the scope of the society was enlarged to include all non-ferrous foundrymen and the name was changed to American Institute of Metals.

At the succeeding sessions of the convention on September 8-11, the program embracing the reading and discussion of a large number of interesting papers was carried out. There was also a banquet of the allied foundry associations at the Hotel LaSalle on Sept. 10 and an industrial excursion, given under the auspices of the Chicago Association of Commerce, on Sept. 11. The American Foundrymen's Association held a convention at the same time, and the Foundry and Machine Exhibition Company gave its ninth annual exhibit at the International Amphitheater, Chicago, during the convention week.

### The New Officers

At the concluding session on Sept. 11 the constitution was revised so that the ten vice-presidents shall be selected from districts representing all of the United States and Canada. Some changes in dues are proposed, but these must be passed upon by the executive committee.

Officers were elected as follows: President, Mr. G. H. Clamer, Ajax Metal Company, Philadelphia; vice-presidents, Messrs. Robert S. B. Wallace, National Cash Register Company, Dayton; W. G. Harris, Canada Metal Company, Toronto; Robert Job, Milton Hersey Company, Montreal; Jesse L. Jones, Oakmont, Pa.; George C. Stone, New Jersey Zinc Company, New York; W. H. Bassett, American Brass Company, Waterbury, Conn.; Fred Moerl, Pullman Company, Chicago; Jacob G. Kasjens, Brass Foundry Company, Peoria, Ill.; H. W. Gillett, United States Bureau of Mines, Washington, D. C.; E. B. Horne, Packard Motor Car Company, Detroit; secretary-treasurer, W. M. Corse, Buffalo, N. Y.

The registered attendance was about 100. The papers relating to metallurgy, metallography and melting practice were discussed on Sept. 10 and 11. In introducing the papers relating to metallurgy of copper, zinc, tin and antimony President Clamer said that there was a great deal of uncertainty among users as to the exact metal content and characteristics of these metals.

### Commercial Classification of Refined Copper

The paper by Mr. Lawrence Addicks, of Douglas, Arizona, on the above subject points out that the world's copper supply comes from four main sources, sulphide ores, oxidized ores, native ores and scrap.

Perhaps the chief chemical characteristic of copper is its affinity for sulphur and the largest deposits of copper ores consist of more or less complex sulphides.

Metallurgically there are three typical processes for producing crude or unrefined copper from the ore, based on the general principles of oxidising sulphides and reducing oxides—(*a*) roasting, smelting and converting, (*b*) alternate oxidation and reduction and (*c*) direct reduction of oxidized ores.

(*a*) which is a strongly oxidizing process by which the great majority of the American production is made from sulphide ores, results in the almost complete elimination of impurities which have volatile oxides, including some of the worst enemies of refined copper, such as arsenic. Converter bar nearly always runs 99 per cent copper plus silver and is not likely to carry more than a few hundredths of a per cent of any impurity but nickel. (*b*) is the old Welsh process, still used to some extent abroad, based upon the reaction between copper oxides and sulphides to eliminate sulphur as sulphur dioxide gas and carried out in a long series of roasts and fusions in reverberatory furnaces. The removal of impurities is here imperfect although they may be to a certain extent segregated in a portion of the product, whence the origin of the "Best Selected" copper of Great Britain. When the ores are wholly oxidized the copper may be recovered by direct reduction in a blast furnace (*c*) and as this is a strictly reducing process the resulting black copper seldom runs over 96 per cent, due to iron and other impurities reduced.

Except in the case of "Best Selected" and similar English coppers, all of the products from the foregoing processes are given a further treatment or refining, which may be broadly divided into furnace or fire refining and electrolytic refining.

Fire refining is based upon the scorifying effect of cuprous oxide upon base metals contained in a bath of molten copper. The crude copper is melted in a reverberatory furnace and air blown into the bath. Cuprous oxide rapidly forms and dissolves in the bath, the blowing being stopped at or before the saturation point. In this way oxygen is carried to all parts of the molten bath and when there are any metals present which are more easily oxidized than copper, cuprous oxide is reduced back to copper and the oxide of the impurity is formed. If this oxide is not soluble in the molten copper it will float to the surface where it may be removed by skimming. As copper stands high among metals in the order of nobility the metallic impurities with the exception of the precious metals may be readily removed in theory. In practice while elimination proceeds rapidly while considerable quantities of impurities are present, the rate diminishes until traces are reached which cannot be slagged off with any reasonable amount of scorifying. Therefore furnace refining is limited in its application to relatively pure crude copper unless a low-grade refined copper is contemplated. Less than ten dollars worth of silver and gold per ton will justify electrolytic refining.

Returning to the bath of molten copper which has been skimmed clean, it is necessary to reduce the excess cuprous oxide dissolved, and no better way has yet been devised than the old Welsh process of covering the bath with a protecting layer of charcoal or low-sulphur coke and then forcing the butts of green trees or poles of hardwood beneath the surface by means of suitable tackle. The cuprous oxide is reduced in this way until a normal amount corresponding to an oxygen content of from 0.04 to 0.07 per cent is left when the copper develops its best physical characteristics, the condition of the copper being followed by the appearance of the fracture of small buttons cast in a spoon or "say ladle" which is a sort of ductility test and by the swell or depression of the surface of an ingot as it cools, which indicates the gas content. The copper is then cast by means of one of the several types of ladling machines which have been very successfully developed in recent years.

When the copper is to be electrolytically refined it is first given a rough furnace refining and cast into anode plates, which are then electrolyzed in a strongly acid solution of copper sulphate. The same order of nobility applies, but the great preponderance of copper over the impurities is now an aid as it assists the selective action of the current in depositing only copper at the cathode. Silver and gold are also saved as they are insoluble in the electrolyte chosen and fall to the bottom of the tank as anode mud or slimes to be separately refined and parted.

Copper entering an electrolytic refining entirely loses its identity. Electrolytic cathodes should be very pure. They generally run about 99.95 per cent Cu, much of the missing 0.05 per cent probably being hydrogen. The metallic impurities generally total about 0.02 per cent.

Except for the fact that individual cathodes may vary more or less in impurity content they are ideal material for brass making. Copper producers, however, have never encouraged the sale of cathodes, as there is apt to be some shrinkage in weight during shipment owing to the comparative ease with which nodules or small pieces can be detached either accidentally or intentionally. Also cathode shipments unbalance the work in a refinery in proportion to their magnitude, as melting cathodes into market shapes is a distinct part of the process.

This melting is done in a reverberatory furnace and originally was an exact duplication of the fire refining already described. As the cathode copper is already pure, a simple melting is all that should be required, but molten copper is so susceptible to contamination that until recently the gases from combustion, iron in the rabbles, etc., were absorbed to a sufficient extent to require actual refining. At the present time large quantities of cathodes are being added to the molten charge during ladling and earlier, basic furnaces are being substituted for acid ones, thereby suppressing slag formation, and attention is being paid to keeping coal ashes from blowing over from the firebox, so that a true melting without refining is being approached.

It is well known that cathode copper when drawn into wire will show an electrical conductivity some two per cent higher than the same copper after a subsequent fire refining. This is probably due partly to the fact that chemical impurities in the cathode are chiefly present as a mechanical mixture due to adherence of anode slimes which are dissolved in the copper when melted, making a high resistance matrix around the copper crystals when the metal is cast and cooled; and partly to contamination during melting. It seems probable that the conductivity of perfectly pure soft copper is in the neighborhood of 103 per cent of the Matthiessen standard in common use.

Lake ores are low-grade native copper deposits, which are mechanically concentrated to an 85 per cent mineral. High-conductivity Lake copper (from the surface ores) cannot be distinguished from electrolytic copper, while low-conductivity Lake copper (from increasing mine depths) is really an alloy of copper with arsenic which has certain desirable properties for special uses. Nearly all the elements which markedly depress the conductivity when alloyed with copper are helpful in developing desirable mechanical properties, for example, phosphorus, aluminium, and silica. High arsenical copper running about 0.4 per cent arsenic has now a special market for making firebox plates in Germany, and uses are found for the intermediate grades.

One of the large Lake companies maintains its own electrolytic refinery, and in this way recovers a small amount of silver and eliminates the arsenic, the product still being classed on the market as Lake, although it is equally electrolytic. The old prejudice in favor of Lake on general principles has now largely died out but only with the contemporaneous retirement of the older generation of wire mill managers. Lake copper should be clearly graded by arsenic contents into a series of alloy coppers, the class at one end competing with electrolytic on its own ground, and the other classes sold in competition with arsenical copper from other sources, a field which has only lately been properly appreciated.

The last class of copper produced, which is considered by Mr. Addicks, is that generally known as casting copper, "a very loose term covering a multitude of sins." Specifications for Lake and electrolytic copper may be readily drawn and after a thorough investigation the American Society for Testing Materials has issued a set which should be generally accepted by engineers, as it has already been by the large refineries and wire mills. Casting copper presents a specification problem hopeless of solution at the present time.

In the second part of his paper Mr. Addicks considers the uses of copper. Electrical uses immediately impose a conductivity requirement which rules out everything but electrolytic and high-conductivity Lake, which, as stated, are practically identical coppers. Most of the electrolytic refineries figure on averaging about 100 per cent soft in the electrical conductivity of their outputs. Occasional lots may reach nearly to 101.0 per cent and some may approach 99.0 per cent, while 98.5 per cent is the usual rejection limit, but it is very unusual for a refinery to ship anything for electrical use which is below 99.0 per cent.

No distinction is made between cakes, wirebars and ingots, more than one shape often being cast from a single furnace charge, so that there is nothing to be gained by ordering wirebars, and then cutting them up when ingots are desired. Unless electrical use is specified it is customary to allow an additional leeway of one per cent in conductivity to the refiner, but he rarely needs this and prefers to maintain the higher standard, as copper is often resold several times before it comes into the hands of the actual user.

When copper is not to be put to an electrical use conductivity is of no special value except as a certificate of the absence of more than a trace of a certain class of impurities. The refiner divides impurities into three classes; those that depress conductivity, such as arsenic and antimony; those that impair ductility, such as lead, tellurium and bismuth; and those which are of value if reclaimed, such as silver, gold, platinum and palladium. The elements which depress conductivity are kept within bounds by the conductivity test regularly made. Those which are of value if reclaimed will never reach quantities sufficient to affect the physical properties of the copper as it would pay to re-refine any such copper. The remaining class comprising elements which impair ductility is more difficult to deal with. We know that bismuth, lead, tellurium and probably selenium make copper very brittle even when present in very small quantities. We do not know, however, how to write a specification limiting these impurities as the presence of small amounts of other impurities will neutralize their bad effects. We do know that amounts of lead up to 0.005 per cent have no perceptible effect in mill practice or in alloys. Double this amount shows mild effects. Lead is about the only one of the group ever met with in sufficient quantity to be of interest. As these elements are practically insoluble in copper their effect on the conductivity is proportional to the amount and consequently negligible.

A representative analysis of refined electrolytic copper of 100 per cent conductivity (annealed) is as follows: copper 99.93 per cent, oxygen 0.04, nickel 0.004, iron 0.0035, sulphur 0.003, antimony 0.003, arsenic 0.002, lead 0.002, aluminum 0.001, silver 0.001, selenium 0.0005, tellurium 0.0005, gold 0.00001, phosphorus and bismuth traces.

It will be seen that oxygen is the chief impurity. It has been pretty conclusively shown that too much oxygen makes the copper harder and affects the annealing temperature, the tensile strength of wire, and the number of breaks in a wire machine. This may be due to some surface effects as the "set" surface of a wire bar has a greater oxygen content than the body of the bar and as the oxygen content increases it is possible that this oxidized layer becomes thicker. Another point about high oxygen is that it corresponds to low copper content and to that extent is sold as copper.

In brass making the "set" or "pitch" of the ingot is of no consequence except when the most careful work is done when melting in the foundry to avoid further absorption of oxygen. It is obviously useless to impose rigid conditions upon the refiner if the same conditions are not observed in the remelting and it is only at the largest and best equipped brass foundries that such conditions are even approached. When zinc is introduced into molten copper it acts as a deoxidizing agent, forming zinc oxide. If the copper is kept at very high pitch this source of zinc loss and dirty brass can be greatly diminished and this fact has resulted in a demand for high copper contents in ingots.

It has therefore become a general custom to specify that the copper contents of refined copper shall not be less than 99.88 per cent, which really means 99.90 per cent, allowing 0.02 per cent for assay variations. As this is a rejection point the actual average content is expected to be between 99.92 and 99.94 per cent.

When we come to casting copper a far greater leeway must be allowed as already pointed out. In fact, except in considering the price charged for the material, copper content as but little to do with casting copper. It is best to buy this material on the basis of known brands after finding what brands yield good results in the particular class of work and then insist upon uniform deliveries, judging the material by chemical analysis of the chief impurities.

The physical defects of refined copper are many. Practically all cast copper is porous, doubtless due to the discharge of dissolved gases as the copper cools.

This is analagous to the "piping" of steel ingots but is not so pronounced because copper is cast in a shallow mould instead of on end. These microscopic bubbles are doubtless the cause of roughness in wire. Then there is a class of defects inseparable from ladling, consisting of cold sets and splashes where the copper has run up on the mould and chilled before the main body of metal reaches that point. Then there is porosity or sponginess of the surface due to the mould being either too hot or too cold. Another defect is raised edges on the set surface, generally due to slightly lowered pitch corresponding to excessive oxygen content of the copper. Should the pitch drop still lower "nigger heads" or little black spots will appear. These are the outlets of gas cavities extending some distance into the copper. On the other hand, should the oxygen content be too low the surface of the bar rises and finally breaks open or "spews," an even worse condition.

Many of these defects are always present in more or less degree. Mechanically ladled copper can never be perfect. Specifications require that copper shall be free from mechanical defects, but a reasonable attitude regarding minor troubles on individual pieces is generally necessary to the peace of mind of a buyer. On the other hand, a refinery occasionally becomes careless in such matters and will send out some surprisingly bad work, so that careful systematic inspection combined with an attitude of friendly criticism is the best way for a copper producer and a copper user to live together.

In Mr. Addicks' absence the paper was read by Secretary Corse. In the discussion which followed President Clamer asked why Lake copper sells at a premium over electrolytic if there is no actual difference.

Mr. W. H. Bassett, of the American Brass Company, Waterbury, Conn., in answer, said that the electrolytic people contend that there should be no premium. The Lake people have argued that inasmuch as Lake copper is a natural deposit it has a longer grain than the electrolytic. Mr. Bassett thinks that probably the whole difference lies in the care with which the product is handled in the refining process. Buyers soon ascertain by experience the reliability of the various producers.

President Clamer said he had heard that if James Cooper had lived Lake copper would not be selling at a premium. When it first appeared electrolytic copper was not of the same good quality as has since been attained by its producers. Perhaps the early prejudice against this copper still exists, although at the present time it is probable that it is only a prejudice. Mr. Clamer spoke of a new process of making brass, in which the zinc is added to the copper in the ladles without reheating.

### The Production of Zinc

Mr. George C. Stone, of the New Jersey Zinc Company, New York, read a paper on "Spelter—Manufacture and Properties." He supplemented it with some reports of tests of various alloys of lead and cadmium with spelter. He also displayed lantern-slide pictures showing how spelter is produced.

The first part of Mr. Stone's paper gives a concise summary of the development of zinc metallurgy and a review of the most representative zinc furnace designs. In the second part the author deals with the impurities in spelter (lead, iron and cadmium) and the effects of these impurities and gives figures on the mechanical strength of spelter. A few notes are added on the limitations of refining processes.

Dr. H. W. Gillett, of Washington, D. C., Mr. Gilbert Rigg, of the New Jersey Zinc Company, and others discussed the properties of various mixtures of cadmium with zinc. The question was discussed whether the occupational disease known as "brass shakes," sometimes experienced by workers in brass foundries, is encountered in zinc smelters. Mr. Stone said he had never heard of a case being caused by pure zinc.

Mr. Bassett said "shakes" do not appear to leave any permanent ill effect, although the attack is disagreeable. Cadmium will give the same symptoms, but more violent.

Dr. Gillett expressed the opinion that copper-vapor poisoning is of a different nature.

### Metallurgy of Tin and Antimony

Mr. William A. Cowan, of the National Lead Company, New York, read a paper on "The Metallurgy of Tin and Antimony."

The first part of Mr. Cowan's paper dealt with tins and gave a summary of representative methods for the analysis of pig-tin for lead, copper, iron, antimony and copper, arsenic, silver, sulphur, phosphorus, tungsten and stannic oxide. This is the outcome of a co-operative analytic research carried out by Mr. D. M. Buck, of the American Sheet & Tin Plate Company, Mr. A. H. Knight, of Liverpool, Mr. A. M. Smoot, of Ledoux & Co., and Mr. J. G. Smith, of the National Lead Company. The different methods of analysis used by the different investigators were described.

The second part of the paper dealt in a similar manner with the metallurgy of antimony and methods of analysis.

At the conclusion of the paper Mr. Cowan made the interesting statement that at the outbreak of the present European war the price of tin rose from 30 cents to 70 cents a pound, but dropped soon after to 35 cents. The price of antimony rose from 5 cents to 15 cents and then dropped to 10 cents. At present the price of tin in New York is about 10 per cent higher than in London. Mr. Cowan illustrated his address with pictures and gave some analyses of samples from ingots of commercial tin and antimony.

President Clamer remarked that the Addicks, Stone and Cowan papers were prepared by authorities on the subjects presented. They are very valuable, for in the case of some of these metals, it is true that very few users know exactly what they have been getting.

### Effects of Repeated Remelting on Copper

In the absence of the author, the paper prepared by Mr. **F. O. Clements**, of the National Cash Register Company, Dayton, Ohio, on "The Effects of Repeated Remelting on Copper" was abstracted by Dr. H. G. Dorsey, of the same company. The interesting experiments described were illustrated by lantern-slide pictures.

The paper gave the results of a series of tests in which the effect of repeated remelting on the soundness of castings was quantitatively measured by an Upton-Lewis fiber stress or endurance machine and chemical tests were made to determine the amount of impurities absorbed during the melting process. The results are given in Table I.

Table I

Physical Data

| | Virgin Metal | First Heat | Second Heat | Third Heat | Fourth Heat | Boron Suboxide | Sample of Boronized Copper Cast Under Ideal Conditions |
|---|---|---|---|---|---|---|---|
| A. B. | 1515 | 850 | 845 | 762 | 334 | 2007 | 3044 |
| R. | 100% | 97% | 96% | 96% | 96% | 103% | 117.5 |
| B. | 2.7% | 5.5% | 4.9% | 8.5% | 22.6% | 2.7% | 0.74 |
| | | | Chemical Data | | | | |
| Copper | 99.78% | 99.59% | 99.49% | 99.43% | 99.39% | 99.56% | |
| Lead | None | Trace | Trace | Trace | Trace | Trace | |
| Sulphur | 0.03% | 0.06% | 0.08% | 0.11% | 0.13% | 0.08% | |

In Table 1 "A B" represents the average number of alternate bends, "R" the resistance offered by the test bar to the bend, given in percentage, assuming the virgin metal to be 100 per cent; "B" the percentage of drop-off of resistance in 10-in. lengths. The toughness of the material is in direct proportion to the figure B.

The last two sets of figures included in table I show very conclusively the value of boron suboxide as a flux. Following the directions of the General Electric Company, two ounces of boron suboxide were added to 16 pounds of the badly injured metal. The copper was heated to 1260° Centigrade, in order to secure the best results from this particular flux. The metal was then allowed to cool down to a casting temperature of 1149° Centigrade, and again cast into ingot form. The ingots had a good appearance, were solid, and the fiber seemed remarkably close, as is evidenced by the results obtained on the endurance machine.

Still again, through the courtesy of the General Electric Company, results are given from a small casting of boronized copper produced under ideal conditions. The copper was both melted and cast in a vacuum. No admission of air during the entire process—such a process with electric source of heat and boron suboxide as a flux, permits absolutely no contamination from oxygen and sulphur—high quality fibre should be the result.

There was considerable discussion of this paper by President Clamer, Dr. Gillett, Messrs. C. P. Karr, of Pittsburgh, Frank A. Clark, of Rome, N. Y., R. S. B. Wallace, of Dayton, Secretary Corse, and others.

Dr. Gillett said that it was not shown to a certainty that sulphur was the impurity causing the deterioration on remelting.

Mr. Wallace spoke of some recent tests on aluminium that were remarkable. The second melting produced better results than were obtained with the virgin metal. These experiments are still being continued in the laboratory of the National Cash Register Company. No fluxes are used. President Clamer remarked that the discussion was of considerable importance, as the question of the effect of remelting is always an open one between the foundryman and the metallurgist.

### Alloys of Copper, Tin and Zinc

Prof. S. L. Hoyt, of the University of Minnesota, read a paper entitled "The Ternary Alloys of Copper, Tin and Zinc—the Kalchoids." This paper, which was illustrated, was of a scientific and technical character. The constitution of the ternary alloys of copper, tin and zinc up to about 50 per cent zinc and 30 per cent tin was studied both by thermal and micrographical analysis. Before a study of the ternary alloys was taken up, an investigation was made of the two binary systems, copper-tin and copper-zinc. The chief results are as follows:

A new heat effect was discovered in the pure copper-tin alloys of the $\alpha + \beta$ range, at 590 deg. C.

In general, the ternary alloys of copper-tin-zinc, up to 50 per cent zinc and 30 per cent tin, were seen from microscopical analyses to behave similarly to the binary alloys of copper-tin and copper-zinc.

The liquidus surfaces, the limit of saturation of the $\alpha$ solid solution, and the eutectoid lines and surfaces were determined.

The eutectoid surface was found to have a maximum near the middle, corresponding to 66 per cent copper, 17 per cent tin, 17 per cent zinc and 590 deg. C. on the eutectoid line. This line shows the $\beta$ solid solutions to be isomorphous.

The addition of tin to the brasses causes the visible breakdown of the $\beta$ solution. The amount of the tin necessary varies with the zinc content and with the rate of cooling through the critical range. This gives rise to abnormalities in the microstructure as explained above.

A field of the $\alpha + \beta$ range in the bronzes was found, in which two heat effects in the solid were recorded, corresponding to the pure copper-tin alloys.

In the discussion Dr. Gillett spoke of the importance of the work of Professor Hoyt in relation to the composition of bronzes. Mr. Clamer spoke of mixtures used in the alloys employed for bearings by railroads, and the importance of knowing the effect of zinc in copper-tin mixtures. Mr. Frank mentioned the fact that zinc and phosphorus do not mix well.

### Melting Practice and the Use of the Electric Furnace in Brass Foundries

Several papers related to melting practice, particularly the use of the electric furnace in brass foundries. The first paper on this subject was read by Dr. **Herbert G. Dorsey**, of the National Cash Register Company. The speaker described "Tests on Electric Furnaces for Brass Foundries." The furnace under test was a 100-kg one of the Helberger type, made by the Allgemeine Elektricitaets Gesellschaft of Germany. Dr. Dorsey described the construction of the furnace and the tests made with this furnace under operating conditions. His final conclusions are as follows:

"Considered commercially, from our standpoint this furnace is a failure. It shows many disadvantages and very few advantages. As a laboratory furnace, including experimental work in the foundry on new combinations, it possibly is a good type of furnace, provided a suitable crucible can be obtained, because almost any temperature may be reached and easily maintained for any considerable length of time, and if only a few heats were to be made per week, the occasional renewing of crucible, resistor, plates, etc., would not be bothersome. To prevent contamination of the metal, some other crucible material would be necessary. On fifty-five heats, five different crucibles were used on an average of only eleven heats per crucible. Working at the above basis no more than eleven or twelve heats could be melted per day unless the furnace were operated at night which would mean a new crucible every day. Unless an air blast were used, to cool it, the furnace would scarcely get cool enough during the night to insert the crucible the next morning. Assuming ideal conditions it would require about 31 kw hours per cwt. to melt the metal, while the above tests show about 62 kw hours per cwt.

"Another disadvantage of the furnace is the fact that the crucible is long and narrow and it is difficult to charge the metal in any quantity unless the furnace tender stayed right with it and put it in piece by piece. This would mean that it would require one tender for each furnace which would be rather expensive. In a more convenient form, the crucible would be a short cylinder of large diameter, but electrically this would be bad as it would necessitate greater currents.

"These tests seem to eliminate the Helberger furnace in our own foundry as a competitor with pit fires. We are now working with other types of furnaces, but have not yet had trials enough to reach any conclusions."

Dr. Gillett said that this paper gave the first account of commercial work with the electric furnace in a brass foundry. Because the Helberger furnace did not succeed under the conditions of the work at Dayton, it does not follow that all electric furnaces are inefficient. Dr. Gillett also pointed out that in considering electric-furnace operation the energy needed to heat the furnace before work is begun must be taken into consideration.

### Electric Furnace for Medium Temperature

A paper on this subject was contributed by Mr. Ernst M. Schmelz, of Detroit. It was read by Secretary Corse and described a furnace which is an evolution of the well-known Stassano type of steel furnace, being built on the same principle, with such particular features added as the lower melting temperature of the charge requires. An experimeneal furnace of this type has been tested at the plant of the Titanium Alloys Manufacturing Company at Niagara Falls, N. Y., Mr. N. Petinot of this company being one of the patenters.

Figs. 1 and 2 show a longitudinal and a cross-sectional view of the furnace. The melting chamber is lined with magnesite, and has an oval section consisting of a semicircular bottom and top, and two straight side walls. There is also an outer lining of fire brick, and the whole furnace is enclosed in a steel shell, and either stationary on its base or supended on two trunions in case it is desirable to use a tilting arrangement instead of the tapping hole.

The heating medium employed is the pure electric arc created between the points of two or more electrodes which enter the furnace from the side. At the points of entering there are water-cooled jackets for the protection of the electrode holders the details of which are shown in Fig. 3. These electrode holders have to be protected from excessive heat and therefore are built hollow and contain an inner tube electrically insulated, from the other parts of the electrode holder, which tube is connected with a water-cooling system. The regulation of the electrode is affected by small hydraulic cylinders placed underneath the water jackets. They are double-acting and governed by four-way cocks mounted on a little standard beside the furnace.

It is evident that if water under pressure is admitted behind the piston of the hydraulic cylinder, this piston and the piston rod will move out and thereby force the electrode holder, with which it is rigidly connected, to move in the same direction, and increase the space between the electrode points. This causes a decrease in the amount of amperage, entering the furnace at a given constant voltage, and correspondingly decreases the heat in the furnace. The reverse movement of the piston will, of course, have the contrary effect, and by this simple and quick-acting system a perfect and smooth regulation of the furnace operations is assured, doing away with all complicated electric starting and regulating apparatus.

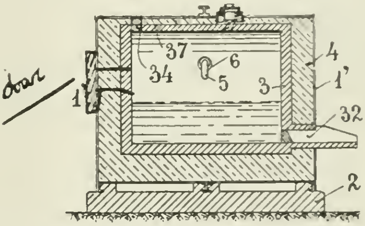

FIG. 1—SECTION OF MEDIUM-TEMPERATURE ELECTRIC FURNACE

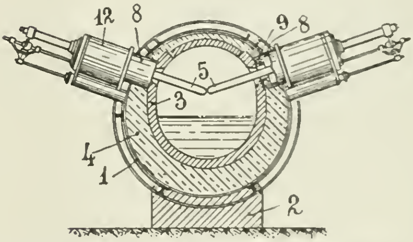

FIG. 2—SECTION OF MEDIUM-TEMPERATURE ELECTRIC FURNACE

To protect the charge from an excessive heat the electric arc is placed approximately in the center of the open space between the surface of the bath and the roof, and on the other hand to prevent a rapid destruction of the roof, and the second or outer lining is much thinner where it covers the roof than on the bottom part of the furnace, owing to the eccentric location of the melting chamber in regard to the outer shell.

The raw material is brought into the furnace through one or more charging doors in the sides which can be tightly closed, which arrangement in combination with the air-tight construction of the electrode holders and stuffing boxes admitting the electrodes affords the special feature of this furnace of a complete neutral atmosphere during the whole time of operation.

In regard to the practical use of this furnace it has several obvious advantages over any ordinary melting furnace using oil or gas as fuel. The use of electricity, the only absolutely pure heating medium, prevents the introduction of any impurities like sulphur, etc., fom the fuel into the charge and the hermetically closed melting chamber affords a complete control over the total process from a metallurgical point of view. Both these features unite in keeping the heat efficiency far above the one obtainable in an open-draft furnace.

An experimental furnace of 120 kw melted 1000 pounds of red copper in less than two hours, using 240 kw-hours per ton of metal, or 0.12 kw-hour per pound. A larger type will, of course, show a tendency to decrase the melting time as well as the amount of electric energy used per ton of molten metal.

The furnace can be designed for the use of D. C. or A. C. current, either single or three-phase and with a voltage of 75 to 220 volts, according to the size of the furnace. The number of cycles is immaterial. The power factor is high, 90 per cent and higher.

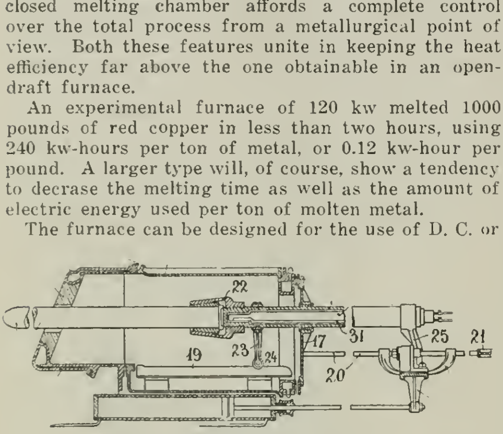

FIG. 3—ELECTRODE HOLDER DESIGN

The regulation is simple and uses no electrical apparatus, but only a hydraulic arrangement, working on about 30 pounds pressure, which are obtainable most anywhere by simple connection with the city water system. No special transformers or starters are required and the furnace can be operated on any private or public lighting and power plant without fear of disturbing other users.

The upkeep of the furnace is economical, the repairs of the lining can easily be done at night or over Sunday and the electrode consumption is small on account of the closed melting chamber, which prevents any excessive burning out of electrode material under the influence of the oxygen of the air.

Dr. Gillett said in the discussion that it was probable that greater uniformity of metal could be obtained by using the electric furnace than in the case of the fuel-fired furnace. One use of the electric furnace is in the melting of cathode copper as produced by electrolytic copper refining. While open to conviction, the speaker expressed himself as skeptical in relation to arc furnaces for melting copper and zinc. The arc-furnace people should produce their figures.

As to frequency, Mr. Corse said that he understood that 25-cycle energy was all right for melting copper. Mr. Corse added that he understood that Mr. Petinot had had some trouble caused by the rapid destruction of his electrodes.

Dr. Dorsey said that so far as he had learned arc furnaces are not adapted to brass melting.

### The Central-Station Point of View

Mr. H. M. St. John, of the Commonwealth Edison Company, Chicago, read a paper on "Electric Brass Melting from the Central-Station Viewpoint." The larger central station companies are rapidly becoming convinced that it is worth while in many instances to give a helping hand in the experimental development of promising processes which use electric power. With respect to the use of electric furnaces for melting brass, as with other processes of a similar nature, it is the mission of the central-station company to act in an advisory capacity to its customers. In order to fill such a role intelligently it is necessary to do a great deal of investigation and experimental work. The needs of the customer must be accurately known and the central-station man must be able to recommend the furnace and method of operation which most satisfactorily meet his peculiar requirements.

The largest single item of cost is the cost of the electric power. Two distinct types of furnace will find use, the "crucible lift-out" type in which the metal is melted in a crucible which is lifted bodily from the furnace and carried to the moulds when the metal is ready to pour, and the tilting type, in which the metal is melted in the furnace chamber and poured into a heated ladle when ready for use. In general the tilting type is the more efficient, but for certain purposes the crucible type is preferred despite its lower efficiency.

The author gives in Table II the results of preliminary tests made on two furnaces, one of the crucible lift-out and one of the tilting type, and gives an estimate as to the approximate power requirements per ton under three systems of operation: (1) Continuous operation for 24 hours a day, (2) ten-hour operation, and (3) "special ten-hour operation" in which case some power is maintained during the night sufficient to keep the furnace hot.

**Table II—Approximate Power Per Ton**

| Metal. | Mode of Operation. | KW Hours Per Ton<br>Lift-out Furn. | <br>Tilting Furn. |
|---|---|---|---|
| Yellow Brass | Continuous | 400 | 280 |
| Yellow Brass | 10 hour | 580 | 400 |
| Yellow Brass | Special 10 hr. | 540 | 397 |
| Red Brass | Continuous | 500 | 350 |
| Red Brass | 10 hour | 720 | 500 |
| Red Brass | Special 10 hr. | 640 | 467 |

In further tables costs of power are given for the regular power rates of the Commonwealth Edison Company of Chicago and an approximate comparison of melting costs is made between fuel and electric furnaces. From the figures obtained the following general conclusions are drawn:

"The ordinary oil lift-out furnace will hardly turn out more than eight heats, or about 0.8 of a ton per 10-hour day. If the furnaces are kept hot over night the electric lift-out furnace will increase this by 25 per cent, the tilting furnace by 50 per cent. The net cost of melting is such that the electric lift-out furnace can be used to considerable advantage in melting yellow brass where continuous or 20-hour operation is practicable. When the furnace is kept hot over night the electric furnace, working 10 hours per day, shows a net cost of melting so close to that of oil that increased production and improved working conditions may be considered factors of sufficient importance to swing the balance in its favor. The electric lift-out furnace does not make a good showing in melting red brass; the tilting furnace is much better adapted for this work.

"In melting yellow brass the tilting electric furnace is more economical than oil under any conditions of operation, and its saving is very marked with either red or yellow brass if continuous or 20-hour operation is used. Special 10-hour operation shows a melting cost for red brass a little higher than of oil, but greatly increased production and improvement in working conditions are in its favor.

"To sum up the present situation, the writer believes that we are safe in saying that a reliable electric melting furnace can be used to advantage wherever 20 or 24-hour operation is possible and in many cases where the regular 10-hour day is the rule. It is well to remember also that the electric brass furnace has at this time only started to realize the possibilities of its development and its reliability and efficiency are sure to be largely increased in the near future."

At the conclusion of the paper President Clamer said that proprietors of small brass foundries could not think of installing electrical generating plants to supply energy for electric furnaces. The electric service companies are greatly interested in this subject. It sounded like a foundryman's dream to have the heat come into the establishment over a few wires.

Mr. Frank Schutz, foundry foreman of the H. Mueller Manufacturing Company, Decatur, Ill., gave it as his opinion that it is only a matter of a short time when all brass founders will be using electric furnaces. He said that difficulties were encountered when the oil-fired furnace was first used, but these have been overcome. Similarly, the electric furnace will make its way.

### Economy of the Electric Furnace

The government Bureau of Mines is studying the metal losses which are encountered during the melting of brass and other non-ferrous alloys in the effort to find methods of reducing these losses. Dr. H. W. Gillett is the alloy chemist of the Bureau of Mines, and he presented a paper on the subject, "Melting Losses in Electric Brass Furnaces," prepared by himself and Mr. J. M. Lohr.

The authors first give a review of the melting losses in fuel-fired brass furnaces on the basis of Bulletin 73 of the Bureau of Mines (H. W. Gillett, Brass Furnace Practice in the United States). The metal losses on non-ferrous alloys fall into two classes; first, losses due to metal entrained in the slag and skimmed off before pouring, and to the spilling of metal in pouring or to spilling metal over into the ashes or coal or coke furnaces during melting and to the spilling of metal in pouring. This class of losses are not primarily due to the furnace, but to a greater or less degree of carelessness in the operation of melting and pouring. These losses can be minimized by care.

The second class of losses, however, is due to the conditions in the furnace itself. These losses are due to oxidation of the metal melted while in the furnace, and to the volatilization of zinc from zinc-containing alloys. Metal lost in these ways is not recovered.

Figures of the losses are given as they occur in actual practice under best conditions of operation as well as under average conditions.

There are two main problems requiring solution before electric furnace for brass melting can be put on a commercial basis: First, is the melting loss sufficiently reduced by electric melting to give it a real advantage on that score over the common methods? Second, can the electrical efficiency of any type of furnace which had advantages in regard to metal losses be made high enough so that the cost of power is not prohibitive?

All electric furnaces for brass melting are still distinctly in the experimental and development stage. Hence the development of electric brass melting has not at present progressed far enough to justify a discussion of the various types in regard to the second problem above outlined.

The Bureau of Mines, in its study of electric furnaces for brass melting has, however, made a number of tests on several types of furnaces with particular attention to the question of metal losses. The results are given in the present paper.

From tests with an indirect arc furnace it is concluded that while it is quite possible that an indirect arc furnace may be so designed and run as to give low zinc losses, yet on account of the high temperature of the arc, it will require careful operation to avoid local over-heating and to reduce the losses below those of fuel-fired furnaces. The tests cannot be considered conclusive on this type of furnace, but so far do not look at all promising on the score of metal losses.

On the other hand, tests of an overhead resistor furnace and the crucible lift-out furnace give loss figures on all the alloys tested that show a considerable saving over the losses of even the best run fuel-fired furnaces.

"The figures given on the crucible lift-out furnace can doubtless be duplicated or closely approached on any form of electric furnace that can be tightly closed and in which there is not excessive local overheating. Crucible furnaces with a carborundum resistor and the Hering furnace should give losses of the same order of magnitude as those in the tests cited, although in these furnaces where no carbon monoxide is given off through oxidation of the resistor, it may be necessary to keep the atmosphere of the furnace chamber reducing by some means such as that of dropping in oil, suggested by Fitzgerald, in order to prevent oxidation of the charge. Tilting furnaces will probably give a slightly higher loss, not because of greater loss during melting itself, but because the metal is more exposed to the air and there is more opportunity for volatilization of zinc, during the double pouring from furnace to ladle and from ladle to mold, than in the single pouring from crucible to mold in a crucible lift-out furnace.

"While the problem is not yet settled in regard to arc furnaces, the data set forth in this paper shows that on a number of types of electric furnaces the metal losses, particularly from alloys high in zinc, are very low, as they should be, according to theory. The figures are sufficiently encouraging to make the development of electric furnaces for brass melting worth the time and labor it will take to bring them to the point where the power consumption is low enough to allow them to compete on an over-all cost basis, with fuel-fired furnaces, and thus allow the brass industry to stop the drain on our mineral resources that is now being made by the metal losses in brass melting."

The bulk of the work was done on brass having 16 per cent of zinc, which was poured at about 1,200 deg. Cent. The net result was that it was found that the losses were reduced to one-half or one-third of what they would be in good practice with fuel-fired furnaces. Dr. Gillett remarked that to get good efficiency the electric furnace must be run pretty fast. In his judgment, it is going to pay the brass founder to buy electrical energy, because the resulting saving will show in economy. Co-operation between the founders, the electric furnace builders and the central-station people is needed and is, indeed, in evidence. But it is to be remembered that the electric furnace for the brass foundry has not yet been sufficiently tested, so that the savings mentioned in the paper may be obtained under foundry conditions. There is still much experimental work to be done. Manufacturers are wisely holding back electric furnaces until they are perfected.

The advent of the electric furnace in the brass foundry will be slow but sure. However, it will never compete with fuel-fired furnaces where metals are now melted down without loss or with losses of less than 1 per cent. But where, as with many of the non-ferrous metals, the losses in melting are a large factor, the electric furnace gives promise of effecting a saving. In fact, the electric furnace in brass melting is no longer a wild hope, but may be regarded as a certainty.

President Clamer said that Dr. Gillett's work was of great value to the industries represented in the American Institute of Metals.

### Use of Gas in Brass Melting

Mr. **E. B. Guenther**, of Detroit, gave an abstract of a long paper entitled "The Use of Producer Gas for Melting Yellow Brass." The paper gave the result of tests conducted jointly by the Detroit Copper & Brass Rolling Mills Company and the Westinghouse Machine Company on a producer gas-heated furnace in the casting shop of the former company. Mr. Guenther did not seem to have much use for the electric furnace. He declared that there is at least one plant where producer gas is used for melting brass under commercial conditions, whereas there is not one in which the electric furnace is used. A gentleman connected with the Langsenkamp plant, where producer gas is used both for engine drive and for fuel in furnaces, said that the coal used is Pocahontas mine run and that the consumption is 8 tons a day.

Mr. **Fred L. Wolf**, of the Ohio Brass Company, Mansfield, Ohio, gave the substance of a paper prepared by himself and Mr. **Robert B. Burr**, entitled "Tests of Natural Gas-Fired Brass-Melting Furnaces Under Factory Operating Conditions." The object of these tests was to endeavor to increase the efficiency of the furnace by making use of the present equipment without entering into too great an expense for alterations. The gas was obtained from the medium pressure mains. The air necessary for combustion was obtained from an independent blower outfit which was installed so that any air pressure up to 32 ounces could be obtained at will, as the highest available pressure, under factory conditions when all equipment was in use, was approximately 14 ounces. The results of our tests showed that by a proper burner construction and manipulation, as efficient results could be obtained with 4 ounces of gas and 14 ounces of air, as with higher pressures, and with, of course, a consequent reduction in the cost of compressing the air.

The experience of the authors shows that where the shell or drum of the ordinary pit type of coke furnace is sufficiently large to allow a reasonable thickness of lining this furnace equipped with a simple tube burner and pre-heating coils, which allows the use of low pressure gas and air, is as efficient as any of the more complicated furnaces tested. Its maintenance cost is practically nil, which applies to the burner also, and our experience shows that it may be continuously operated without delay for repairs and with no inconvenience to operators.

### Pyrometers

Dr. H. W. Gillett summarized an exhaustive paper he had written on the subject of "Pyrometers for Molten Brass and Bronze," in which radiation pyrometers, optical pyrometers and thermo-electric pyrometers are classified. He described an improved thermo-electric instrument in which a composite protective tube is used, the body being silfrax, but provided with a tip of molybdenum, which is not attacked by hot molten brass or bronze. However, according to the speaker, there is not yet any pyrometer which can be considered an all-around practical foundry tool.

### Electric Brass Melting with the Hering Furnace

Mr. **G. H. Clamer**, of Philadelphia, gave, in brief abstract, a paper written by himself and Dr. Carl Hering on "Electric Brass Melting."

In the paper the general advantages of electric furnaces for brass melting are first discussed, and it is pointed out that the ideal method would be to melt and pour as quickly as possible, hence in as small lots as the particular conditions of the foundry require, though this, of course, need not be carried to extremes. It is thought, however, that for small castings at least a high power tilting brass furnace of this type could be constructed small enough to be transported to the molds, pouring directly into them.

A description of the general construction of the Hering pinch-effect furnace is then given, and it is pointed out what a large amount of heat is carried out of the heating holes in the furnace bottom ("the resistors") effectively by the rapidly flowing metal; it exceeds that of a row of electric arcs in those holes. At present about 25 to 50 kw. are converted into heat in each hole (or roughly about 90,000 to 200,000 B. T. U. or 20,000 to 45,000 kg. cal. per hour), with the probabilities that this can be considerably increased. The correct proportioning of these holes and the current are of great importance. These proportions are quite different for brass than for steel. The furnace must be especially designed for each metal, though variations in the compositions of brasses and bronzes can be taken care of in the same furnace by regulation of the electric current.

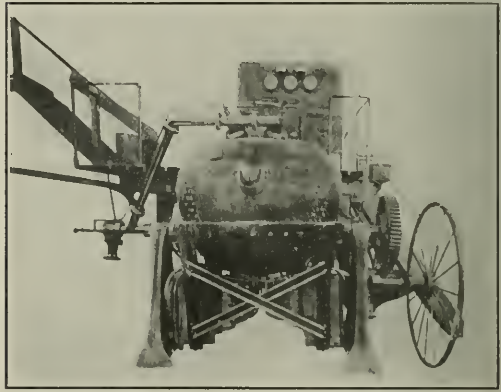

FIG. 4—TWO-PHASE PINCH EFFECT FURNACE

Even copper with its very low resistance can be melted commercially in these furnaces without requiring impractical proportions. The higher the electrical resistivity of a metal the better the proportions become.

The power factor of the furnace, even with 60 cycles, is not low, being "in the eighties and nineties, and even this small reduction from 100 per cent was no doubt largely, if not all, in the transformers and could be avoided in a better design of the transformers. In a steel furnace with a frequency of 25 the power factor was practically 100 per cent, hence perfect."

The Hering furnace has so far been used for melting very light brass and bronze chips, which gave trouble in the fuel furnaces. In melting many tons of these light, curly and oily brass chips with much mechanically mixed iron, they cast in the form of clean ingots nearly 8 pounds per kw. hour, delivered to the furnace transformers, equal to about 12.5 kw. hours per 100 pounds poured. But there were various losses which can be avoided in future. Short runs, with clean ingot charges, indicated that, even with the easily avoidable excesses in the losses, 10 pounds per kw. hour could be obtained in this furnace, hence, in better designs, even still better efficiencies than this can reasonably be expected. But this figure depends largely on the amount of superheat required by the particular foundryman.

The economy of the electric melting could be greatly increased by preheating the charge with a fuel flame, preferably in an auxiliary furnace, to only such a temperature at which no oxidation takes place.

L—Electrode Lugs

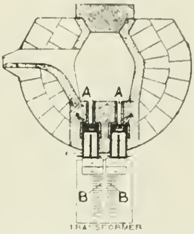

FIG. 5—JACKET AND ELECTRIC CONNECT FOR 120-KW TWO-PHASE PINCH EFFECT BRASS FURNACE

Comparisons are then made between the operation costs of fuel-fired and electric furnaces for brass melting. Finding as an average 38 cents per 100 pounds for coke furnaces and 20 for the electric, the saving in a plant melting 20 tons per day, would be nearly $22,000 per year of 300 days; or for oil furnaces at 43.2 and electric at 20 cents, the saving would be nearly $28,000 per year, which should be credited to the first cost of the electric furnace.

The development of the Hering type of furnace involved many difficulties largely because it was an entirely new and somewhat radical departure from existing practice, hence no precedents existed. The troubles encountered in its development were chiefly in finding the proper proportions of the electric parts for which no precedents existed and which could be determined only by trial, involving the erection and destruction of many experimental furnaces. The electric resistivities of the molten metals had to be determined as they were not then known to the art. The electrodes, which are of metal, are necessarily liquid at their hot ends and solid at the cold ends, hence must be carefully designed and proportioned, so that on the one hand they do not melt back too far, and on the other hand do not carry off too much of the heat. The undesirable circulation or washing of the metal at the hot ends of the electrodes where they join the heating holes has been avoided by a special construction of the electrodes.

The outside of the 110 kw. furnace is shown in Fig. 4. It is a two-phase furnace. The two transformers are seen underneath; they tilt with the furnace. For each transformer there are two vertical heating holes, thus making each transformer independent of the other. A three-phase furnace with three transformers, three electrodes and three heating holes would be better.

Fig. 5 is an outline and diagrammatic vertical cross section in which R are the heating holes or resistors.

In a later and better design the hearth, electrodes and heating holes are arranged as in Fig. 6, which makes the relining and repairs of the heating holes easier than when they are at the bottom, as they are in Figs. 4 and 5. This improved form also permits turning around the spout as a center, which is considered by many to be an important advantage, and which does not exist in the form in Fig. 4.

The furnace shown in Fig. 4 has been criticised for being so large outside. These large outside dimensions are not essential and the furnace could have been made far smaller for the same capacity of metal if desired or by using an outside lining of kieselguhr brick. But thick walls economize heat, which is more important in electric than in fuel furnaces, as the cost per unit of heat is, of course, greater. Our argument was that bricks are cheaper than kilowatts, hence that the first investment in thicker walls was more economical than to suffer the continued losses of expensive kilowatts.

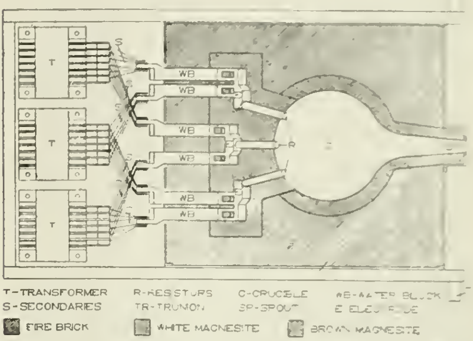

FIG. 6—150-KW THREE-PHASE PINCH EFFECT FURNACE

The Hering furnace will soon be in regular, 24 hours per day, operation at the foundry of the Ajax Metal Company in Philadelphia, they having made very satisfactory terms with the local power supply company.

Reports of a number of other papers had to be reserved for our next issue.

## A New Aluminium Alloy

A London company has placed on the market a new alloy named "Ormiston Metal," after its inventor, Mr. H. O. Ormiston, of Sydney, Australia. The metal, which is white and bright, contains about 97.5 per cent of aluminium, and can be produced either directly from bauxite clay with the addition of the requisite chemical compounds, or by alloying pure aluminium. It is stated that this metal will take a polish equal to that of silver or nickel, which it retains permanently, and that it is not corroded by the atmosphere, by sea air or by food acids. For equal weights its electrical conductivity is greater than that of copper or any known alloy. Tensile tests taken at the National Physical Laboratory show a strength of 16 tons per square inch, and tests in Australia went up to 20 tons. Perhaps the most important claim is that it can be soldered either to itself or to other metals with an ordinary soldering iron or blow-lamp and can be brazed or welded without difficulty.

---

**Transvaal Gold Production.**—The number of companies reporting to the Transvaal Chamber of Mines in June, 1914, was 60. The total quantity of ore milled during that period was 2,233,507 tons. There were 9,803 stamps in operation with an average duty of 8.82 tons per 24 hours. Tube mills in commission numbered 294. The yield for the month was 717,926 fine ounces gold.

# Notes on Chemistry and Metallurgy in Great Britain

*(From Our Special Correspondent)*

### The War and the Engineering Industries

Considerable dislocation of most of the British industries inevitably occurred during the first two weeks of the war, but there are manifest signs that the difficulties are being grappled with firmly and will soon be overcome. In the steel trade, particularly in Scotland, the cessation of the supply of continental material has been rather severely felt by engineers and shipbuilders, while the supplies of ore for the furnaces are by no means equal to the demand. In the Tyne district there has naturally been a large increase of work in the shipyards, and the Elswick works are as busy as they can be. At Sheffield some of the works not engaged in the production of war material have been put on short time, but the increased activity of those that are so engaged compensates for the temporary adverse condition of the others. In South Wales there is every prospect that the iron and steel industries may anticipate a period of renewed prosperity, and probably a considerably higher output than has ever been previously attained. Birmingham, of course, produces a great output of war material, and large orders from government have been placed with the Birmingham Small Arms Company and other concerns.

Mechanical engineers in general are not so lucky, and the wholesale cancelling of orders has been acutely felt. In the Swansea district the tin-plate workers may safely look forward to a vastly improved condition of affairs. More than 100 tin-plate mills in this neighborhood will shortly be re-started, and it is estimated they will employ upward of 5000 hands. The engineers of Liverpool are more fortunate than some of the others. A large influx of government orders has been keeping practically all the works very busy, while there is every sign that this brisk state of affairs is likely to continue for a considerable time.

As a result of the ability of the British navy to keep practically the whole of the trade routes at sea free from interference, the alarm which was so general during the first week or two of the war has almost totally subsided, and it is not too much to hope that the British engineering industries will very soon resume a condition, not perhaps quite normal, but at all events approaching it.

### The Féry Gas Calorimeter

The determination of the calorific value of gas involves, at present, the use of expensive and intricate apparatus under expert supervision, as well as the expenditure of considerable time. M. Féry, the inventor of the well-known pyrometer bearing his name, has now produced a simple instrument which gives a quick and, apparently, a reliable reading. When a flame is inclosed in a chimney the current of the gaseous products of combustion admixed with surplus air has a velocity proportional to the calorific value of the material undergoing combustion. The new instrument consists of a burner and chimney with a cylinder below through which all the air passes; while at the lower end of the cylinder an anemometer is suspended, by its gravitic center, and by angular displacement, indicates the velocity—and, consequently, also the calorific value—on a calibrated scale. The accuracy of the determinations depends on the gas being supplied at a strictly uniform rate, and to ensure this a sensitive governor regulates the flow.

### The Supply of Tungsten

Several months ago it was pointed out in these notes that Great Britain was dependent on Germany for practically the whole of the supply of tungsten. But the question of the production of tungsten in England has already been under serious consideration by influential firms connected with the steel trade, and the Luton firm which has for some time past devoted its attention to the production of ferrotungsten and similar alloys will soon be in a position to assist in meeting the requirements of manufacturers of tool steel and other special steels.

### The Iron and Steel Institute

The meeting of the Iron and Steel Institute which was to have been held in Paris in September will, necessarily, now not take place. There were hopes that the assembly would be transferred to London; but it has been decided to abandon the meeting altogether. The papers will be sent to the members by post, and criticisms in writing will take the place of the usual discussions, and will be duly published.

### The Institution of Mining Engineers

The annual meeting will be held on Sept. 9 at Stoke-on-Trent. The following papers are included in those put down for reading: "Absorption of Oxygen by Coal," by Messrs. T. F. Winmill and J. I. Graham; "Self-Contained Rescue Apparatus and Smoke Helmets for Use in Irrespirable Atmospheres," by Dr. J. S. Haldane, and "Unknown Clays in Coal Mines," by Dr. J. W. Mellor. Sir William Garforth will preside.

### The Distribution of Phosphorus in Steel

Among the papers presented in the Engineering Section of the recent Australian meeting of the British Association was one by Dr. W. Rosenhain describing a method of treating steel specimens, elaborated by himself and Mr. J. L. Haughton, which, they claim, brings out structural features much more satisfactorily than do the ordinary etching processes.

The author remarked that, while the deteriorating effect of phosphorus on the mechanical properties of steel is unquestionable, it is hardly credible that less than 0.04 per cent of phosphorus could exert a serious effect if it were uniformly distributed throughout the metal. The reagent employed in their research was a solution of ferric chloride acidified with hydrochloric acid and with the further addition of small proportions of chlorides of copper and tin; and its action was to replace the small amount of iron dissolved from the specimen by an equivalent quantity of copper.

With a steel of ideal purity the film of copper would be quite uniformly deposited on the ferrite, but in the case of steel containing phosphorus compounds the purest portions of the surface are coated first and those parts richest in phosphorus are left bare for a considerable time. When carried to a certain point the appearance of the surface developed by the etching corresponds almost exactly, under the microscope, to that produced by heat-tinting, but with less prolonged action features are brought out which are not revealed by the etching reagents usually employed or by heat-tinting.

From a close examination of these features the author has been led to attribute the origin of the banded structure of phosphoric steel to processes occurring during the first solidification of a solid solution alloy; and he concludes that the coarseness or fineness of the banding in the finished steel is determined by the scale of crystallization which occurred in the original ingot, although the crystalline structure may have subsequently undergone repeated modification by thermal or mechanical treatment.

### Manganese Steel

Among the several Iron and Steel Institute papers which have not yet been reported, one on manganese steel should first be mentioned.

A paper by Sir R. A. Hadfield and Professor Bertram Hopkinson described the magnetic and mechanical properties of the manganese steel containing 12 pe rcent of manganese and 1.25 per cent carbon. When heated to 1000 deg. C. and quenched in water the steel is very tough and almost non-magnetic, but when reheated in the neighborhood of 520 deg. C. for about 600 hours, it will acquire a degree of magnetism about 60 per cent of that exhibited by pure iron. It also requires magnetic properties at lower temperatures, but the change is very much slower.

It was found that the magnetism acquired at 520 deg. C. was not got rid of nor diminished by reheating at 550 deg. C., but that at higher temperatures than 640 deg. there was a rapid diminution and the magnetism was almost completely eliminated after heating for a few minutes at 750 deg. C. Heating curves demonstrated that this sudden change of properties at about 700 deg. was accompanied by a perceptible absorption of heat.

This manganese steel, after cooling in the ordinary way in air, subsequent to casting or forging, is somewhat brittle, hard, and non-magnetic: after quenching in water from 1000 deg. C. it is very ductile but remains non-magnetic, and any treatment of the water-quenched-steel which renders it magnetic to only a slight extent also tends to make it hard and brittle, and when it has acquired one per cent. of the magnetism of pure iron it has lost its toughness to such an extent as to be useless for ordinary purposes.

The hardness generally increases with the magnetism, but the increase in hardness is not comparable with the hardness acquired as a consequence of the accession of the initial traces of magnetism.

Well defined changes in the micro-structure occur during the transition from the ductile to the hard and brittle condition.

### Cause of the Hardening of Metals

In a paper by Professors C. A. Edwards and H. C. H. Carpenter the authors contend that the process of annealing or softening metals by heating to fairly high temperatures and subsequent slow cooling results in the extensive growth of crystals. When alloys, such as carbon steels are quenched, severe stresses are induced which cause marked twinning of the crystals. The greater hardness brought about by quenching steels from a temperature above their highest critical point is directly as the velocity and thermal extent of the suppressed inversion; and the relation between crystal twinning and percentage of carbon is plainly evident.

Dr. Beilby showed that when metals are depressed and hardened by cold working amorphous layers are found on the surface, and similar amorphous layers are found on all surfaces on which twinning takes place. The authors are of opinion that the presence of these amorphous layers is the ultimate cause of hardening by quenching steels. From these effects it appears that the cause of hardening by quenching is precisely similar to that of hardening by cold working, namely, the internal deformation of crystals.

### Direct Production of Steel from Ore

A paper by Messrs. Ernest Humbert and Axel Hethey dealt with the direct production of steel from ore in the electric furnace. The difficulties experienced in the ordinary manufacture of steel in getting rid of oxygen, phosphorous, sulphur, and silicon and the practical impossibility of eliminating hydrogen and nitrogen induced them to experiment on a method of producing steel of a higher degree of purity. They arrived at the conclusion that under satisfactory conditions the electric furnace is suitable for the practical production of high-grade steel direct from the ore; and they claim that the predominent feature of the steel manufactured in their experiments is its great toughness. Forge tests carried out at the furnace showed that even when containing a high percentage of carbon the steel would easily bend without fracture.

### Utilization of the Heat of Molten Slag

The Slag Power Company seems, to a very great extent, to have solved the question of using up the heat in furnace slag. Experiments have been carried on for about four years at Messrs. Bell Brothers' works at Port Clarence, and at last all the difficulties which were encountered in the early stages appear to have been effectually overcome.

The original idea was to use the steam directly produced by the immersion of the slag in water, but the presence of sulphuretted hydrogen, sulphur and other impurities rendered the use of such steam inadmissible in a turbine, and no efficient process could be devised for the removal of those impurities. The method now adopted is to use this impure steam generated by the immersion of the slag in the water to supply heat to a Kestner single-effect climbing film evaporator, and the apparatus has been brought to such a state of perfection that the results are very satisfactory.

It has been ascertained that 1 kg. of slag contains about 550 calories, or 1000 kg. would contain 550,000 calories, and after allowing for loss by the heat remaining at 100 deg. C. and the heat in the water absorbed by the slag, estimated at 50 per cent., the net value of 1000 kg. would be 490,000 calories which a further allowance for working loss brings down to some 367,500, which is equivalent to 590 kg. of steam.

In actual practice more than 740 kg. of water have been evaporated by 1000 kg. of furnace slag, and the average efficiency of the evaporator is approximately 91 per cent; but even at 80 per cent. the pure steam which could be used for turbines amounts to 472 kg., which, with a steam consumption of 13 kg. per horse power is equivalent to 36 horse power per 1000 kg. of iron slag.

Of course, in estimating the economy, the cost of the plant and labor have to be taken into consideration, and when the steam thus generated is used in a low-pressure turbine it is estimated that with a 1000 k.w. plant working at 75 per cent load, the generation of one k.w. would cost 0.32d. as against 0.48d. with a high pressure steam plant and coal at 14s. 6d. a ton, showing a saving of 0.16d. per k.w. in favor of the slag plant—a difference which is calculated to amount to about £4,300 a year at the works in question

### A New Thermopile

The practical difficulties hitherto encountered in the production of a thermopile capable of yielding an efficient and useful supply of electrical energy have been such that the instrument has been almost lost sight of amongst practical men for many years. It has remained for Johannes Marschall, of Dresden to produce a thermopile in which the old difficulties have to a very great extent been overcome, and which promises to be a serviceable source of current to small consumers of electrical energy. In the Marschall pile the positive elements are made of a special alloy of low resistance and high E. M. F., whilst the negatives are of constantan, an alloy of copper and nickel, the junction being made with electro-deposited copper. Five such pairs in series form one section, and the requisite number of sections are arranged in an annular frame with the heated junctions on the inside and the cold junctions on the outside. The required output is obtained by employing a sufficient number of rings arranged in a central heating tube.

But a leading feature of Herr Marschall's apparatus is the furnace which acts as a gas generator in which the gas produced from coal or other suitable fuel is conveyed to the central heating tube, where, admixed with a plentiful supply of air, it undergoes perfect combustion. In the annular space on the outside of the rings of sections cold air is made to circulate at a speed sufficient to maintain the required temperature. Experiments with a pile consisting of ten sections working with the difference of 300 deg. C. between the hot and the cold junctions show an E. M. F. of 0.03 volt per pair.

On this basis it is estimated that a pile containing 1000 pairs would give 1.5 kilowatts at 35 volts, and would measure about 3 ft. in diameter by 7 ft. in length. A pile giving an output of about one kilowatt has been at work for some little time in Dresden, and so far no deterioration has been observed in regard to resistance at the junctions. If the claims which are put forward for the efficiency of this pile should prove valid, as appears probable, the apparatus will be very serviceable for lighting and small power installations, particularly in country districts remote from any power station. There is a growing demand for such an apparatus. But at present we have no information as to either capital outlay or working costs.

### Revised Engineering Standards Specifications

The British Engineering Standards Committee has recently issued a report (No. 68) revising the specifications for the resistance of steel conductor rails for electrified railways. The resistance is to be stated in terms of a rail of the same material as the conductor-rail having a length of 1 yd. and weighing 100 lb. Conversion tables for resistances measured at a given temperature in rails of other weight are appended, together with formulæ for ascertaining in terms of the new standard the equivalents of the resistances of rails expressed in terms of copper, as formerly.

Specification No. 65 provides that pipes hitherto known as "stoneware" pipes shall be described as "salt-glazed ware" pipes. There are two classes of these, viz., "Standard Pipes," made to comply with the specification, only a certain percentage of which need be actually tested by hydraulic pressure, and "Standard Tested Pipes," every one of which must undergo hydraulic test.

All pipes complying with the B. E. S. specification are to have a standard mark.

### Marine Oil Engines and Fire Risk from Sprayed Oil

The Board of Trade inquiry into the loss by fire of the small motor vessel *Scout*, on Loch Leven, last August, resulted in experiments being conducted by one of the board's surveyors which afforded some very instructive conclusions which fully justified the adjournment of the proceedings in order to ascertain whether oil projected from the flywheel of an engine of the type used on the *Scout* would ignite and cause the firing of the boat. The engine room and engine of the *Scout* were reconstructed as nearly as possible, and it was found that when running at 450 r.p.m. any oil that was in the bilge was thrown by the flywheel on to the exhaust pipe. If it were pure lubricating oil it did not ignite from contact with the exhaust pipe, but was vaporized in dense smoke which could be ignited by a naked flame. When glowing points left by burned cotton waste were put on the hot exhaust the oil caught fire, but not readily. With oil of lower gravity and flash point, such as paraffine, in the bilge the spray from the flywheel took fire immediately on coming into contact with the hot pipe.

The court found that the fire which destroyed the *Scout* was so caused.

The danger to be apprehended from sprayed oil is not confined to small boats having engines fitted with flywheels, but extends to all highly heated pipes and machinery where oils of low gravity are employed.

### Public Companies

*Anderston Foundry Co., Ltd.:*

A final dividend of 15/6d. per share is recommended, making £1 per share for the year, less income tax. £40,984 is placed to depreciation and £10,000 withdrawn from the reserve fund four years ago are replaced. The dividend for the previous year was 12s. per share.

*British Electric Traction Co., Ltd.:*

A dividend is recommended of 3½ per cent on the 7 per cent non-cumulative preferred stock, as well as a full dividend on the 6 per cent cumulative preference stock. £50,000 is carried to reserve.

*Marconi Wireless Telegraph Co., Ltd.*—The ordinary general meeting was held July 21 when Commendatore G. Marconi, who presided, said he was afraid the report and figures had been somewhat disappointing to the shareholders; but, from the criticisms he had heard and seen, he judged that the report and the figures it contained had not been correctly apprehended. The reason why the directors recommended a final dividend of 10 per cent was the fact that the large sum of £142,726 5s. 11d. carried forward at the end of 1912 was carried forward for the purpose of averaging dividends after placing £100,000 to special reserve account. Some of the remarks during the discussion were distinctly of an acrimonious character; but the general feeling of the meeting may be gauged from the almost unanimous expression of confidence in the chairman and the board which followed the offers of resignation by the chairman and the managing director.

### Market Prices—August, 1914

The official exchanges being closed, prices are not fixed, and can only be taken as representing private transactions and liable to change at any time. Those given below must be taken with all reserve, and show merely that, owing to precautionary measures, the possibility of violent fluctuations has been avoided.

The London Metal Exchange, after being closed from July 30, reopened from Aug. 18 from 11:30 a. m. until 12:30 p. m., and has been so opened since, but dealings and the making of prices were prohibited, and press publication forbidden.

| | £. s. d |

# Synopsis of Chemical and Metallurgical Literature

## Gold and Silver

**Nipissing Mill and Metallurgical Practice.**—A discussion by Mr. G. H. Clevenger at the Salt Lake meeting of the A. I. M. E. of a paper previously presented to the Institute by Mr. James Johnston. After outlining the status of metallurgical practice at Cobalt prior to the researches by the Nipissing company, Mr. Clevenger states that it was the determination of the Nipissing consulting metallurgists to treat all ore by a hydrometallurgical process and that nothing but refined silver was to leave the premises. The middle ground involving concentration and cyanidation did not appear attractive. "Generally you are attempting to operate a concentrator and a cyanide plant with neither up to full efficiency.". Concentration in combination with cyanidation should be adopted only as a last resort.

The results of preliminary tests indicated that a cyanide plant would be most advantageous. The use of mercury in the low-grade mill was not attractive, and the plan of grinding the whole ore, native silver, dyscrasite, etc., fine enough so that all the silver could be dissolved by cyanide, was finally adopted. Usually when metallic gold and silver occur in ores that are to be cyanided, amalgamation or concentration are resorted to; but in this case the native metal was finely ground for cyanidation. This is a point on which there may be a strong difference of opinion, and which must be determined by conditions.

The author points out that the idea of using a preliminary treatment involving the use of aluminium and caustic soda on precious-metal ores, such as is done at Nipissing, is not new. It was suggested by W. H. Walker in a note on the electrometallurgy of gold, published in the *Transactions* of the American Electrochemical Society, volume four, 1903. This preliminary reduction may not be economically feasible on all ores, and the author urges caution in its adoption. Thus in the Cripple Creek district, where roasting is cheaply done, the wet reduction process might not be profitably adopted, but where roasting cost on telluride ores was high the wet reduction method would merit consideration. In some cases wet reduction might form products that would interfere with cyanide treatment or cause a high cyanide loss. Again, preliminary treatment with caustic soda alone has proven valuable.

Although precipitation by aluminium dust was finally adopted at Nipissing, the author is not convinced that zinc precipitation would have been impossible. The application of aluminium dust precipitation elsewhere must be considered cautiously. Probably its future use will be confined to special cases. One of the difficulties encountered in using this precipitant is the long period of violent agitation necessary, due to a coating of the oxide and stearine, the latter being used in the manufacture of the dust.

The author gives consideration to the relative merits of zinc and aluminium as precipitants and discusses the claim for cyanide regenerated by the use of aluminium. He points out also the chemical value of zinc in cyanide solutions, as potassium zinc cyanide, and the gradual regeneration of cyanide in alkaline cyanide solutions that have been precipitated on zinc.

**Descriptive Technology of Gold and Silver Metallurgy.**—A paper presented at the Salt Lake meeting of the A. I. M. E. by Mr. A. W. Allen, in which the author deals with some inconsistencies of expression used by technical writers and points out fallacies in the presentation of metallurgical results. On the subject of "extraction," the point is made that "extraction and recovery are terms which are not necessarily interchangeable and the time is ripe for due recognition of the fact." The author objects to certain loose methods of calculating and reporting recoveries in metallurgical processes, and points out the necessity of clarity of statement so that comparisons can be made between operations at different mills.

The following definitions are suggested, and formulae given for obtaining the desired results:

**The assay or theoretical extraction** is the amount of metal which is indicated by assay results as having been removed from the ore during treatment.

Where $a$ = the assay of feed,
$z$ = the assay of residue, and
$t$ = the tonnage represented,

$$\text{then } \frac{100\,(a - z)}{a} = \textit{percentage assay extraction.}$$

$$\text{and } \frac{a_1t_1 + a_2t_2 + a_3t_3 + \ldots}{t_1 + t_2 + t_3 + \ldots} = \text{average feed assay} = A,$$

$$\text{and } \frac{z_1t_1 + z_2t_2 + z_3t_3 + \ldots}{t_1 + t_2 + t_3 + \ldots} = \text{average residue assay} = Z$$

$$\text{then } \frac{100\,(A - Z)}{A} = \textit{average assay extraction percentage.}$$

**The actual extraction** indicates the amount of metal recovered from the ore and isolated either as bullion or in other concentrated form. Such actual extraction is estimated by the direct valuation of the bullion and the statement of return from smelter or buyer showing actual metal content in concentrated product, upon which sale was effected.

Where $M$ = the amount of metal in bullion, concentrate, or precipitate,
$T$ = the tonnage milled,
$t$ = the tonnage of concentrated product removed, and
$Z$ = the average actual residue assay,

$$\text{then } \frac{100\,M}{M + Z\,(T - t)} = \text{average actual extraction percentage.}$$

**The actual recovery** can only be based on the direct valuation of bullion, and the term is only available for use when the bullion produced is approximately the same market value, *per se*, as the contained gold and silver.

Where $M$ = the amount of metal in bullion,
$T$ = the total tonnage, and
$Z$ = the average residue assay,

$$\text{then } \frac{100\,M}{M + TZ} = \textit{average actual recovery percentage.}$$

In the statement of working costs, the author urges the segregation of working cost from general expense, and the differentiation between the cost of repairs and renewals. In the statement of construction costs he suggests the exclusion of all sums paid for wearing parts, these being segregated in a suspense account and charged out as operating expense. Attention to these details will prevent large fluctuations in costs and avoid false impressions.

## Copper, Lead and Zinc

**Unit Construction Costs of the Arizona Copper Company's Smelter.**—Probably no paper presented at the Salt Lake meeting of the A. I. M. E. received more commendation than did that of Mr. **E. Horton Jones**, in which unit costs of smelter construction were given. The paper was spoken of as a classic of its kind. Naturally no abstract can be given, and reference must be had to the original paper published in the July *Bulletin* of the Institute. The actual figures are of interest primarily to smelters, but all classes of metallurgists will be interested in the manner of presenting these cost data, and will gain a great deal by studying the article. The subject is presented under five heads: unit costs, comparative costs, composite costs, wage scale and raw material prices. Each cost item is described, and numerous drawings illustrate the types of construction.

**Nodulizing Blast-Furnace Flue-Dust.**—Experience with a 6-ft. by 60-ft. rotary, oil-fired kiln is given in the July *Bulletin*, A. I. M. E., by **Mr. Lawrence Addicks.** Preliminary experiments in a 2-ft. by 20-ft. kiln indicated a fuel consumption of 50 gal. of oil per ton of dust nodulized. Excellent nodules were formed and rings or accretions were absent. In the larger kiln in actual operation, fuel consumption was greatly reduced and rings showed a marked tendency to form. A first-class smelting product could be made with an oil consumption of 12 gal. per ton. The inclination of the kiln was $\frac{5}{8}$ in. per foot, and the speed $1\frac{1}{2}$ r.p.m. Capacity varied: with a clean kiln it was possible to nodulize 75 tons of dust in 24 hours; a choked barrel reduced the capacity half, but regular operation delivered an average of 50 tons per day, including all delays. Experiments with coal firing, operating after the manner of a gas producer, was a failure owing to irregularity in the temperature at the mouth of the kiln. Coal-dust firing was not tried as it gives too high a temperature for nodulizing. The author believes that kiln-nodulizing is worthy of wider use, but suggests that its applicability can be determined only by experiment. "The crux of the whole matter lies in cost of fuel."

**Basic-Lined Converter Practice at the Old Dominion Plant.**—Conditions at the Old Dominion smelter make it necessary to crowd the converter capacity to its limit, and interfere with the systematic operation of the converter. **Mr. L. O. Howard** gives the following record of converter operation, in a paper presented at the Salt Lake meeting of the A. I. M. E.

| | |
|---|---|
| Commenced blowing | Jan. 6, 1913 |
| Taken off stand for patching | June 27, 1913 |
| Total blowing time | 2,689 hr. 40 min. |
| Total number of blows made | 664 |
| Average time of blow | 4 hr. 3 min. |
| Tons matte charged | 18,157 |
| Average copper content of matte | 43.9 per cent. |
| Average time blowing one ton copper | 22.5 min. |
| Total copper made | 7,250 tons |
| Average copper per converter hour | 2.66 tons |
| Average air used per minute | 9,000 cu. ft. |
| Average blast pressure | 13.3 lb. |
| Ore fed | 3,301 tons |

| *Average Slag Analysis* | | *Average Matte Analysis* | |
|---|---|---|---|
| | Per Cent. | | Per Cent. |
| Cu | 2.5 | Cu | 43.9 |
| $SiO_2$ | 22.7 | Fe | 28.8 |
| Fe | 52.1 | S | 22.6 |
| CaO | 0.8 | Ins | 0.4 |
| $Al_2O_3$ | 1.6 | | |

The author describes a difficulty encountered in the closing of the converter mouth due to cooling of the charge when it was necessary to pour from the converter directly into molds at a time when the casting machine was out of commission. Various means were tried for removing the incrustations, but none proved effective until a specially designed collar puller was adopted. This device is lowered into the mouth of the converter from the crane. On lifting, a cutting tooth is forced into the incrustation, loosening it until large pieces can be removed.

Experience with the formation of monolithic magnetite lining on the basic brick is also described.[*] Following is the method used at Old Dominion for applying the magnetite coating: Into a new converter previously heated by coal and coke, charge about 12 tons of molten matte and blow for about 3 hours with silica. Then lower the temperature by the addition of about 4 tons of cold hood cleanings and blow for a short time, when the magnetite will be spread evenly over the interior. More matte and just enough silica to flux the iron therein contained are then added, and the charge finished in the usual manner. The magnetite lining is then maintained by attention to the temperature of converting.

**Smelting Lead Ores in the Blast Furnace.**—In a paper on this subject by **Mr. Irving A. Palmer,** published in the July *Bulletin* of the A. I. M. E., the author calls attention of the modified policy of one of the largest lead smelting companies regarding publication of details of its technical operations, and commends the abandonment of secrecy in this respect. The paper covers many details of lead smelting, and the original must be consulted to get the greatest benefit. Of first importance in the progress in lead smelting in recent years is the adoption of sinter-roasting, as in Huntington-Heberlein pots and Dwight-Lloyd continuous machines. Second in importance is the general use of mechanical methods in handling materials. The bag house has been more generally adopted, and larger furnaces are being built. Water jackets are of soft steel instead of cast iron. Mechanical feeding has been more generally adopted, and the charges are more thoroughly mixed than formerly. In discussing the effect of different ingredients in the charge and the formation of slags and mattes, the author points out the necessity of looking for metal losses elsewhere than in the slag, and suggests that lead is a very elusive metal when in the form of fume.

**The Bag House in Lead Metallurgy.**—In a paper presented at the Salt Lake meeting of the A. I. M. E., **Mr. L. Douglass Anderson,** superintendent of the Midvale smelter of the U. S. Smelting Co., discusses the complete bag house system adopted at that plant in order to minimize damage to agricultural crops in Salt Lake valley. Both blast furnace and roaster gases are thus collected separately. The former present no difficulties, but the latter are hot and contain more or less sulphuric acid, and must be cooled and neutralized. The importance of cooling cannot be underestimated if metal recovery is to be complete. Cooling can be accomplished by passing the gases through thin metal flues, by water sprays and by dilution with external air. Neutralization is done by introducing lime, zinc oxide, or other suitable base into the flues.

The introduction of the bag house has resulted in the accumulation of many elements, such as arsenic, cadmium, tellurium and selenium, which formerly escaped, but which now increase in quantity if a closed circuit is maintained for any length of time by resmelting bag-house residues. At Midvale the arsenic is allowed to build up until the dust is rich enough for treatment in arsenic furnaces for the recovery of white arsenic.

The author mentions the experience with Dwight-Lloyd machines, and the bag-house fires which resulted from the distillation of elemental sulphur into the flue gases. This condition was marked in damp weather and disappeared in warm dry weather. Various schemes were tried to avoid this condition, but they were ineffective. Finally the use of these machines was limited to sintering pre-roasted matte and ores low in pyrite.

**Lead-Matte Converting at Tooele.**—A modification of the usual method of converting leady matte has been adopted at the Tooele smelter of the Internation company. The process was described in a paper read by **Mr. Oscar M. Kuchs** at the Salt Lake meeting of the A. I. M. E. At first it was endeavored to convert copper-lead matte in the usual manner, with the direct addition of silicious fluxing ores; but bag-house troubles developed in the form of acid spots on the bags, resulting in their ultimate destruction. This meant that either the converter fumes must be neutralized by CaO or ZnO, or the production of a fume in itself sufficiently alkaline to prevent the deposition of free acid in the bags. Hence the method was changed, and molten matte directly from the blast furnaces is now blown without the addition of silicious flux, to the almost complete elimination of the lead, and to the production of copper bullion. The lead fume is collected in the bag house, and the copper bullion and heavy iron slag are transferred to converters blowing copper matte. This reduces the copper oxide formed in the first blow of the lead-matte charge, and utilizes the value of the iron slag for fluxing silicious ores. The final slag from the copper converters is then transferred molten to a reverberatory copper furnace. This system has greatly improved conditions in the bag house.

---

[*] Originally described by Wheeler & Krejci, *Bulletin* A. I. M. E., Dec., 1913. See also this journal, Feb., 1914, p. 138.

**Losses of Zinc in Mining, Milling and Smelting.**—In the symposium on zinc metallurgy at the Salt Lake meeting of the A. I. M. E., Messrs. **D. A. Lyon** and **S. S. Arentz** presented a paper in which they discussed the present losses of zinc and the probable methods for reducing such losses. It is stated that probably less than 50 per cent of the zinc mined reaches the form of spelter. The methods of beneficiating and smelting zinc ores are briefly discussed, and the possible future sources of zinc are given, as follows: Present waste in concentration processes, waste in slags of lead and copper smelters, low-grade carbonates, and micro-crystalline ores of zinc, iron and lead.

**Ammonia-Carbon Dioxide Process for Complex Zinc Ores.**—Another paper in the zinc symposium was that of Mr. **S. E. Bretherton**, who advocated the use of the ammonia-carbon dioxide process for the treatment of zinc ores containing precious as well as other base metals. Briefly the process is as follows: Grind the ore, roast, regrind, leach zinc with ammonia and carbon dioxide, precipitate copper from the zinc solution, distill ammonia and carbon dioxide from the solution, thereby precipitating basic zinc carbonate which can then be calcined to oxide. The precipitated copper can be added to the residue, which is then ready for smelting. The basic zinc carbonate can be smelted, or converted into chloride for use as a wood preservative. If the oxide can be made pure white, it can be used as a pigment. The author concludes his paper with a detailed report on test runs in an experimental plant.

## Chemical Engineering.

**Ammonia Analysis.**—In an article by **E. Stach** in *Glückauf* of Aug. 1, 1914,, various new apparatus are described for determining and recording the pressure, speed, and the density of gases and vapors, besides an instrument for determining the ammonia content in liquids. The principle of the latter instrument is that when ammonia is decomposed by hypobromites or hypochlorites, nitrogen is developed in gas form in a quantity proportional to the ammonia to be determined. The equation for an ammonium chloride solution with sodium hypobromite $3NaBrO + 2NaOH + 2NH_4Cl = 2N + 2NaCl + 5H_2O + 3NaBr$. In order to record automatically the result of the analysis the nitrogen set free is measured by the instrument shown in Fig. 1. At *a* the liquid containing the ammonia enters. At *b* the hypobromite is syphoned off. In the measuring vessel *cd* the liquids are kept on a certain level. Through *e* water enters into *fg* and compresses the air in *g* to a pressure which depends on the height of the syphon *h*. This compressed air acts on the liquids in *c* and *d* whereby they are forced into the mixing vessel *i*. Since the compressed air cuts off *k* simultaneously, the nitrogen set free in *i* must pass below the bell *l*, the motion of which is transmitted to the recording drum.

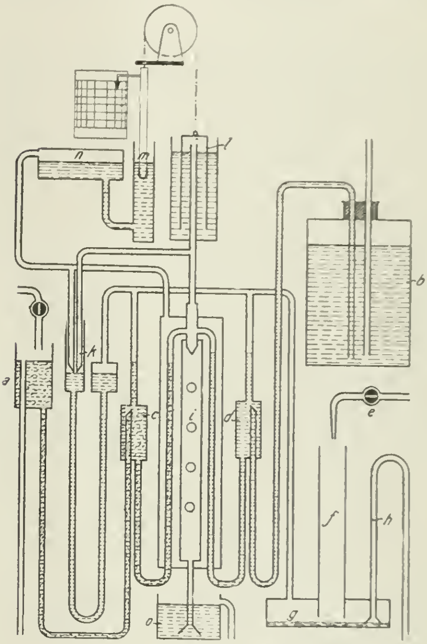

FIG. 1—AMMONIA ANALYSIS

**Sulphuric Acid Towers.**—In the *Chemiker Zeitung* of July 30 Dr. **Georg Schliebs** emphasizes that if sulphuric acid towers are to be substituted for lead chambers, they should be designed and operated accordingly, but this is usually not the case. In the first place, there is not the same opportunity for the gases of getting mixed. In a lead chamber of 1000 to 3000 cubicmeters content the gases remain for half an hour or an hour in continuous motion and mixing, concentrated gases coming in contact with gases which have been already become diluted and so on. Through a tower of 100 to 300 cubicmeters content the gases pass in a few minutes. While there is a perpetual dividing up and reuniting of the gas currents, there is never an opportunity of fresh gases and of diluted gases coming together. In the second place a lead chamber is able to get rid quickly of any excess of heat by simple radiation. The tower has a much smaller radiation surface, moreover, the tower fillings act as a storage or reservoir of heat. Further in a lead chamber the gases are repeatedly heated and cooled, which is impossible in a tower. The author thinks that these disadvantages of the tower can be overcome by the very simple remedy of providing behind the tower an "equalizer" ("Ausgleicher"), that is a vessel in which the acid is removed from the gases, while the gases which are now more dilute and have been cooled may be returned by a special pipe line back to the entrance of the tower so as to pass through it again. He obtains in this way a forced mixing of dilute and of fresh concentrated gases. Further the reaction heat is gotten rid of in a simple way by air or water-cooling. Temperature differences are produced since the warm gases are cooled in the equalizer and are heated again in their next passage through the tower. The output of the different towers and of the whole system may be regulated by this method within wide limits. The towers are better utilized and the expensive supply of acid running down over the filling may be largely reduced. Disturbances in operation and variations in output and temperatures may be equlized before they reach the final towers.

### Radium in Carnotite

**Determination of the Radium: Uranium Ratio in Carnotites.**—The increasing importance of carnotite as the largest known source of radium has made the accurate determination of the radium: uranium ratio in that mineral of the greatest importance. Hitherto investigators have found deviations from the normal ratio, as observed in pitchblende, and the results have usually been low. Hence the impression has gained ground that carnoties are, as a rule, anywhere from a few per cent to 30 per cent lower in radium than would correspond to the uranium content. In order to investigate this matter more carefully, Messrs. **S. C. Lind** and **C. F. Whittemore**, of the Denver office of the Bureau of Mines, conducted a research, the results of which are published in the current issue of the *Journal* of the American Chemical Society. Their work is of great importance to the American radium industry, for they establish the fact that the ratio of radium to uranium in carnotite is identical with that of pitchblende. Their paper describes methods of procedure and gives data on many determinations. Following is a summary:

1.—Samples of carnotite representing *large* quantities of ore (a few hundred pounds to several tons) show a Ra:U ratio identical with that of pitchblende, $3.33 \times 10^{-7}$, which is also in accord with the value calculated from radiation data.

2.—Samples from *small* quantities (hand specimens up to a few pounds) tend to exhibit abnormal ratios, in one instance as low as $2.48 \times 10^{-7}$, and in another as high as $4.6 \times 10^{-7}$.

3.—The most plausible explanation for these ratios seems to be one of "transposition" of radium within an ore bed, producing local differences which are equalized in large samples.

4.—The "emanating power" of carnotite appears high and varies from 16 to 50 per cent.

5.—In order to obtain concordant results by the Boltwood emanation method, it was found desirable to determine the emanation liberated by solution in the same sample from which the emanating power had just been determined, thus making the two determinations strictly "complementary."

6.—Radium may be easily determined by the emanation method in one operation either by solution or by ignition from tubes in which it has been sealed for one month to reach equilibrium.

7.—In contrast with the successful solution or ignition methods for de-emanating carnotite, fusion with carbonate, and also the fusion and solution method both gave low results and were abandoned.

### Corrosion.

**Corrosion of Condenser Tubes.**—A very suggestive article on the corrosion of condenser tubes is contributed to the September issue of the *General Electric Review* by E. Bate, of the New South Wales Government Tramways in Sydney, Australia. The author gives a review of his own experience with pit-hole corrosion. With Rhodin he distinguished between balanced and unbalanced alloys. "Particles of the two constituents of the alloy, infinitesimally close together, will have each a definite solution potential. If these solution potentials balance, then the minimum rate of corrosion is obtained, for if they do not balance, local currents are set up and electrolytic corrosion assists the purely solution or oxidation corrosion. On this theory, and by using the heats of oxidation and molecular weights of copper and zinc, the author arrived at the result that 70 per cent. Cu and 30 per cent. Zn is the best alloy of these two metals." The British Admiralty specifies a mixture of 70 per cent. Cu, 29 per cent. Zn and 1 per cent. Sn.

Its suitability for plants using sea water is, in the opinion of the author, well established. When pit-hole corrosion occurs, however, it is of a local character and is ascribed by the author to local action due to an electronegative particle on a surface positive to it. There seem only two ways in which such a condition can be set up: (1) by segregation in the alloy; (2) by a deposit of electronegative particles on the tube surface. That the second assumption is correct is, at least in his own case, the chief point of the author's discussion and his arguments in this respect are as follows: First, as to the time which it takes for the tube to become pitted completely through he finds that failures start to take place within a month or two after the condenser is put in service, and the average failures per week gradually increase to a steady average rate of failure, with heavy failures now and again. In some cases the trouble may cease after a few months, and the engineer usually concludes that corrosion was due to faulty tubes, which have been eliminated. In several cases the author has found that about the time when failures ceased, some certain treatment of the condensers had been started, which the engineer generally did not connect in any way to the improved conditions. He emphasizes the fact that it is possible to stop failures by methods whose only effect would be to prevent the possible deposit of electronegative material in the tubes, and, furthermore, that the effect is noticeable very rapidly, which points to the fact that corrosion is a phenomenon whose action is very rapid. Further "if corrosion is due to a deposit, then, undoubtedly, we can expect with confidence that the majority of holes will be in the lower half of the tube. This anticipation is most strikingly verified as a result of the author's observations." Of 468 tubes the author found that only 21 had a corrosion hole in the upper half of the tube, the remainder were in the lower half. That corrosion of the tubes under notice took place on the bottom half of the tube has been corroborated by other engineers whose condensers suffered in the same way. Since, therefore, the very strongest grounds were present for suspecting that a dangerous deposit was being left in the tubes, it became important to determine from what source this deposit came.

"The author's attention was directed to the corroding cast iron of the circulating system and condensers as a source of troublesome deposit for the following reasons: Although the circulating water brought through the condensers in question is always very dirty, certain condensers taking the same water have been free from trouble. If, therefore, we consider the water at intake in the harbor as free from deleterious material, the troublesome particles must come from the metal in contact with the water on its way to the condenser. Cast iron, unless carefully protected, corrodes severely when exposed to the action of sea water, and as cast iron is a so-called alloy of carbon and iron with traces of other impurities, the products of corrosion will be mainly oxide of iron and carbon. Carbon is, as previously pointed out, strongly electronegative, and, therefore, of just the nature to cause the trouble experienced. The condensers under particular observation, which gave very serious trouble, were provided with 22 copper stays between tube plate and water box cover at each end, and these copper stays had cast-iron sleeves to form distance pieces between tube plates and covers. There were thus 44 cast-iron distance pieces in the water space of the condenser, all of which were found to be badly corroded, especially close to the tube plate, where they were in close contact with the gun-metal.

To test this theory, the cast-iron distance pieces were removed, and gun-metal distance pieces substituted, while, at the same time, the cast-iron surfaces in contact with circulating water were all cleaned and painted with a protective coating. "The measures above outlined were soon productive of marked diminution in the number of tube failures in these condensers, and it can be definitely stated that, up to the present, no tube put in the condensers since the alterations were made has failed." Stations that take circulating water to the condensers, or to the circulating pump intake in concrete or brick ducts, and use either short cast-iron or entirely gun-metal intakes, should, therefore, not suffer to any appreciable extent from tube corrosion. At the White Bay power-house this policy can be pursued, as the circulating water ducts are entirely of concrete, and the short intake is of gun-metal, the pump body and impeller being of a yellow metal mixture. Inquiries have elicited the information that several plants, which have been free from trouble, have consistently protected their cast iron on general grounds without any idea of thereby preventing the corrosion of condenser tubes. "The author trusts that if the logic of his theory is sound, the result will be a greater confidence in installing large condensing plants, and less anxiety as to the possibility of serious and expensive trouble. It should lead to a modification of those conditions under which large stations draw supplies of sea water through considerable lengths of cast-iron piping, often quite untreated internally, and thus liable to continuous corrosion. The suitability of the Admiralty tube for plants using sea water, when supplied by good makers, is, in the opinion of the author, well established, but tinning of the tube seems unnecessary and dangerous."

---

**Rutile.**—Virginia produced all the American output of rutile in 1913, according to the United States Geological Survey, the deposits being located at Roseland, Nelson County. During the year the company which controls and works these deposits produced 305 tons of rutile, valued at about $49,000. A large part of the rutile produced in 1913 was used in the manufacture of titanium carbide electrodes for arc lamps. A part of the ilmenite found in the deposits and separated by means of amagnetic separator has been sold for use in making electrodes for electric lights, and the experiments with the electric furnace point to the possible use of ilmenite in the direct production of tool steel.

**Tungsten.**—The tungsten resources of the United States are probably considerably larger than have been generally realized. Many new deposits have been discovered in various parts of the Western States, according to the United States Geological Survey, and, should prices advance, it is probable that the output could soon be increased much above the record year of 1910, when 1821 tons were marketed. Most of these new discoveries are not sufficiently developed to show how large an output can be expected from them; but it is probable that some will prove to be of considerable extent, and one or two new large producers would make a noticeable difference in the American market.

## Recent Chemical and Metallurgical Patents

### Iron and Steel

**Briqueting Fine Ore.**—An improved method of briqueting fine iron ore, flue dust and the like, has been patented by **Walter Mathesius**, of Charlottenburg, Germany. The invention consists in the employment of a binding medium which will react with a part of the iron in the material to be briqueted. Alumino-silicates of a highly basic nature are mixed with ferric hydroxide and water, and this binding medium then mixed with fine ore. If the addition of ferric hydroxide has not exceeded a certain limit, the binder will react with further quantities of ferric hydroxide or oxide, and yield products having the properties of a cement. The binder should be mixed with the ore in as fresh a state as possible. The quantity of ferric hydroxide in the binder should not exceed one molecule for each three molecules of the bases contained in the alumino-silicates. From one to two per cent of the alumino-silicates is sufficient to form firm briquets. Portland cement blast furnace slag or like products of calcination or fusion containing the necessary quantity of lime can be used as the basic alumino-silicates. Burnt lime also may be used, but in that case the binder must be formed by grinding the lime with fine iron ore in water, and after heating to accelerate the reaction between iron oxide and lime, mixed in a fresh state with the material to be briqueted. The whole is then molded and allowed to set. In order to lower the fusing point of the briquets and thereby prevent disintegration before fusion, certain addition agents may be used, such as the oxides of magnesium, strontium or barium, or small quantities of titanic acid. (1,104,124, July 21, 1914.)

**A Method of Incorporating Titanium into Iron** has been patented by **Mr. Auguste J. Rossi**, of Niagara Falls, N. Y., and assigned to the Titanium Alloy Manufacturing Co., of New York City. Relatively high temperatures, say 2500 deg. C. or higher, are required for the production of titanium-iron containing relatively high percentages of titanium, say 10 per cent. The inventor has discovered, however, that lower-grade titanium irons, containing say from 5 to 1 per cent of titanium, can be made at temperatures of the open-hearth or blast furnace, say from 1500 to 1700 deg. C., provided there be present, during some stage of the operation, manganese in the elemental state. He cites the fact that titaniferous iron ore containing as high as 40 per cent titanic acid, when smelted in the usual manner, will yield iron containing little or no titanium, but when smelted with manganese in the charge, the resulting iron will contain as much as 5 per cent of titanium. The invention can be practiced by incorporating into any approved furnace charge, comprising titaniferous iron ore, fuel and fluxes, oxide of manganese in the form of manganiferous iron ore, so that nascent manganese will be present during the reduction. The titaniferous iron ore should contain at least 3 per cent titanic oxide, and manganese should be present in quantity not less than equal to 10 per cent of the titanic oxide. (1,104,317, July 21, 1914.)

**Ore Reduction.**—A novel proposal for the reduction of iron and other ores that are not volatile at a temperature of 800 deg. C., is contained in a patent granted to **Buenaventura Junquera**, of Oviedo, Spain. In brief, it is proposed to fine-grind the ore, fluxes and carbon for reduction, and feed the mixture at one end of a rotary furnace. The furnace is fired from the opposite end with pulverized fuel. The reduction of the pulverized mineral in contact with the reducing carbon is very rapid and occurs in the front end of the furnace at a temperature of 600 to 800 deg. C. When the mixture of reduced metal and flux reaches the high-temperature zone of the furnace (1500 to 1600 deg.) fusion occurs and the slag and metal are discharged into a receiver. The inventor claims that by his process iron ore can be converted in twenty minutes into molten iron containing 0.10 per cent carbon. The consumption of fuel for converting ore of 50 per cent iron into metal is about 1000 kg per ton of metal obtained, of which about 600 kilos is used for reduction and 400 for combustion. (1,102,339, July 7, 1914.)

**Preparation of Flue-Dust and Fine Ore for Smelting.**—In order to agglomerate fine ore and flue-dust and make a product suitable for charging into a blast furnace, Mr. **William Cooper**, of Denver, Col., proposes to inject into piles of such material a liquid hardening medium, such as a thin solution of cement. The grout thus formed is allowed to harden, after which the pile is broken into lumps. The binding material is forced into the pile through perforated pipes driven to the bottom. (1,103,400, July 14, 1914.)

### Gold and Silver

**Preparation of Refractory Ore for Cyaniding.**—The wet desulphurizing process used at the Nipissing mill, Cobalt, Ontario, whereby the refractory silver sulphide, sulpharsenide and sulphantimonide minerals are decomposed and rendered amenable to cyanidation, depends in principle on contact of the pulverized ore with aluminium in alkaline solution. A description of the work at Nipissing appears elsewhere in this issue. In a patent recently granted to Mr. **Charles Butters**, the process is outlined as follows: "The invention is based on a reaction which it has been found occurs when sulphide gold and silver ores, tellurides, and similar ores associated with, or not associated with, arsenic, antimony and the like are brought into intimate contact, such as by agitation or otherwise with certain metals such for example as aluminium, zinc, tin or palladium, in any convenient form, but preferably as metallic surfaces, in the presence of caustic soda or other caustic alkalies, either hot or cold, which results in such ores being decomposed and the metallic gold and silver being freed from combination with the sulphur or the like, whereby they are in condition to be readily attacked or dissolved by potassium cyanide or other suitable solvents. * * * Under these conditions an electric current is set up between the aluminium and the ore under treatment, the aluminium acting as the anode and the ore as the cathode, which latter, probably principally through the agency of nascent hydrogen, is then split up into its component parts, and the precious metals left free to be acted on by cyanide or other suitable solvents." Equations showing the effect on argentite are as follows:

$$2Al + 2NaOH + 2H_2O = Na_2Al_2O_4 + 6H$$

$$6H + 3Ag_2S + 6NaOH = 3Na_2S + 6H_2O + 6Ag$$

For gold telluride, the equation is:

$$AuTe_2 + 2Al + 4NaOH = Na_2Al_2O_4 + Na_2Te + 2H_2Te + Au$$

It is gathered from the patent specifications that the process is of wider application than that now known to be used at Nipissing. (1,103,346, July 14, 1914.)

**Chlorination of Ores.**—Frequent references have been made of late in technical literature[1] to processes for chloridizing low-grade ores containing gold, silver, copper and lead, according to methods devised by **N. C. Christensen, Jr.**, and **T. P. Holt**, of Salt Lake City, Utah, and to the mills utilizing such processes. In a patent recently granted to these men (Christensen assigning his interest to George H. Dern, of Salt Lake City) they disclose details of operation and furnace construction, practically as used at Park City, Utah, by the Mines Operating Co., under the direction of Messrs. Dern & Holt.

The preparation of the ore is accomplished by grinding, mixing with about 2 per cent of fuel, unless the ore contains fuel such as sulphides, mixing also with salt, and finally adding moisture varying from 5 per cent for coarse, non-absorbent ore, to 15 per cent for fine, absorbent material. The mixture is then roasted in a shaft furnace, such as illustrated in Fig. 1, in which air is forced through the charge from beneath, and in which certain zones are maintained as indicated in the figure. In this manner a counter-current flow of ore-mixture and air is achieved. The roasted ore is withdrawn from the bottom of the furnace and fresh mixture added from above. The roasting zone is always within the furnace charge and protected by roasted ore below and unroasted mixture above. The roasted ore is lixiviated with acidified water and the metal is precipitated from the solution as explained in previous articles to which reference has been made.

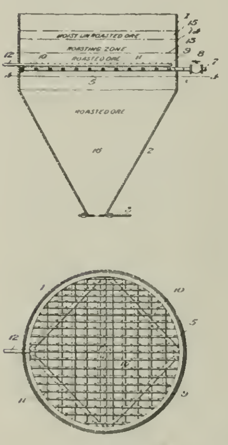

FIG. 1 — FURNACE FOR CHLORIDIZING-ROASTING

The furnace shown in the figure consists of a circular or square upper part 1 and a conical or pyramidal lower portion 2. The air-blast pipe 5 is disposed about the upper portion and connected with cross pipes, all having openings on their lower sides. A stirring grate 9 is placed just above the air pipes, and by its operation the roasted ore is gradually removed from the roasting zone and discharged through the gate 3 at the bottom. In starting the furnace, it is filled with roasted ore up to the level 13. A layer of live coals is then prepared and on this is charged the green mixture; the blast is applied, and the operations of discharging roasted ore and charging green ore proceed as desired. Gases from the furnace are dustless and are conducted to absorption towers to produce liquor for lixiviation. (1,107,240, Aug. 11, 1914.)

**Slime Filter.**—A new method of applying vacuum filtration to ore slime is disclosed in a patent granted to Mr. **Walter E. Trent**, of Reno, Nevada. As shown in Fig. 2 the filter consists of two wheel frames mounted on a shaft, with swinging filter pans or trays disposed between the spokes of the wheels, after the manner of a "Ferris" wheel. Each filter pan is connected with a source of vacuum through the pipe frames that constitute the spokes of the wheel which, in turn, communicate with the hollow central shaft. Feed is delivered to the filter pans through pipes that revolve with the frame and connect with an annular launder at one end of the shaft. Washes of water and solution can be applied as desired, and the filtered cake is discharged by automatically tipping the pans as they approach the point of discharge. As each pan is weighted, it resumes its horizontal position after dumping, when it is ready to receive a new charge. (1,097,896, May 26, 1914.)

**Another form of vacuum slime filter** on which a patent has been granted to **George Ridgway**, of Kalgoorlie, Western Australia, consists of two tanks to hold the slime pulp and wash solution, filter frames through which the slime is filtered, and rocking arms the transfer the frames from one tank to the other after the successive functions of filtering and washing have been performed. During the passage back from the wash tank to the slime tank compressed air is admitted to the filter leaves and the slime cake is discharged. Automatic reversing gear and valve trips govern the operation of the filter. (1,103,080, July 14, 1914.)

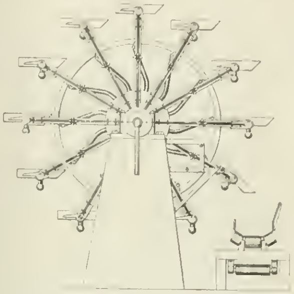

FIG. 2—VACUUM FILTER

### Lead and Copper

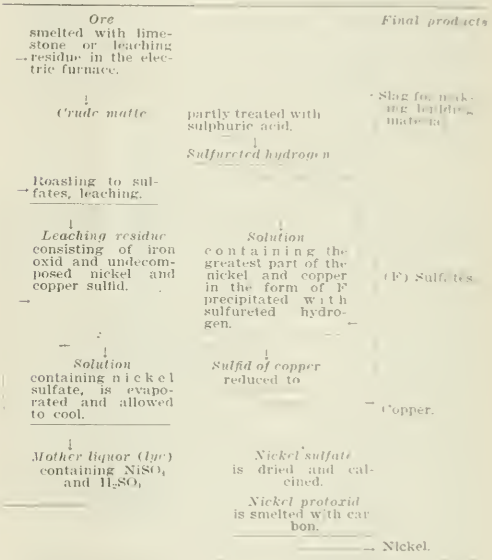
**Refining and Desilverizing Lead Bullion.**—An improved method of arranging and operating a plant for refining and desilverizing lead bullion by the Pattinson process has been patented by **William Thum**, of Hammond, Ind. According to this process, lead bullion containing silver is agitated with air or steam, and intermittently sprayed with water, with the effect of crystallizing the lead and leaving a liquid enriched portion containing the silver. The lead settles to the bottom of the kettle, while then enriched bullion floats above, as well as permeating the mass of lead crystals. The two portions are then separated, each being transferred in opposite directions through a series of kettles. The resulting desilverized bullion is cast for sale and the enriched portion for refining by electrolysis or cupellation or other form of refining. The transfer of the respective portions has hitherto been accomplished by raising the kettle being tapped, or lowering the receiving kettle, or by means of large ladles handled by cranes.

The present invention makes use of air pressure for the transfer of the products through the series of kettles, thus avoiding movement of the kettles and permitting a fixed arrangement. The kettles are constructed so that they can be removed from their settings in case of renewal or repair. (1,106,480, Aug. 11, 1914.)

**Reducing Cuprous Chloride.**—A patent has been granted to **Frederick Laist**, of Anaconda, Mont., for an improved method of reducing cuprous chloride in such a way as to regenerate the chlorine as a chloride salt suitable for reuse in chloridizing oxidized copper solutions. The method has relation to Mr. Laist's previously patented modification of the Hunt & Douglas method of leaching copper ores with sulphuric acid solution, containing also sufficient chlorine, in the form of a soluble chloride, to form the subchloride with the copper. Having dissolved the copper from an ore with the solution above mentioned, cuprous chloride is precipitated by treatment with sulphur dioxide. According to the present invention, in order to regenerate the chlorine therein contained for use on further lots of ore, the cuprous chloride is reduced with carbonate of calcium or sodium and carbon, whereby copper is reduced and the chlorine is combined with calcium or sodium. The latter can then be used to chloridize new oxidized solutions of copper. Mr. Laist's original patent is 903,732, Nov. 10, 1908 and was referred to in this journal Dec., 1908, page 510. (1,104,907, July 28, 1914.)

### Copper, Nickel and Zinc

**Treatment of Copper-Nickel Ores.**—In our issue for January, 1913, page 55, we presented an abstract of a patented process for the recovery of copper and nickel from low-grade ores and products, the inventors being Professor **Wilhelm Borchers**, of Aachen, Germany, and **Harold Pedersen**, of Trondhjem, Norway. It has now been discovered by the inventors that their process can be simplified in its latter stages, and they have secured an additional patent. Following is a synopsis of the improved process.



Ore smelted with limestone or leaching residue in the electric furnace.
Final products
Crude matte
partly treated with sulphuric acid.
Slag for making building material
Sulfureted hydrogen
Roasting to sulfates, leaching.
Leaching residue consisting of iron oxid and undecomposed nickel and copper sulfid.
Solution containing the greatest part of the nickel and copper in the form of F precipitated with sulfureted hydrogen.
(F) Sulfates
Solution containing nickel sulfate, is evaporated and allowed to cool.
Sulfid of copper reduced to
Copper.
Mother liquor (lye) containing NiSO4 and H2SO4
Nickel sulfate is dried and calcined.
Nickel protoxid is smelted with carbon.
Nickel.

The earlier patent is No. 1,043,291, Nov. 5, 1912; the current patent is 1,101,115, June 23, 1914.

**Separation of Zinc Blende and Barytes.**—The difficulty attending the mechanical separation of blende and barytes by ordinary methods of concentration are well known. According to specifications of a patent granted to Mr. **Charles J. Greenstreet**, of Webster Groves, Mo., a separation of these minerals can be effected by mixing them with a salt such as the chloride, sulphate or bisulphate of sodium and fusing the mixture. Under these conditions the barytes is mechanically combined and held in suspension with the molten sodium salt, while the blende is unaffected. The mixture eventually separates into two layers with the salt and barytes on top, and a separation can be made. On dissolving the salt, barytes is again precipitated. (13,735, Reissued May 26, 1914.)

### Rare Metals

**Vanadium.**—Two patents granted to **Harold Boericke**, of Vanadium, Colo., disclose the inventor's modification of the usual manner of treating vanadium ores by roasting with sodium chloride to form soluble sodium vanadate. The objections to the usual procedure are the high temperature required for the reaction and the consequent high fuel consumption. Mr. Boericke states that he has found that by the addition of a sulphide or a sulphate to the mixture the reaction takes place at a much lower temperature, with consequent reduction in the fuel consumption, and without material effect on the production of soluble vanadates. Thus 1 per cent iron sulphate added to the mixture has effected a saving of 50 per cent of fuel and has increased the capacity of the furnace 100 per cent. In case iron sulphide is added, it is first converted to sulphate during the reaction, after which it gives the same effect as though the sulphate were added originally. (1,105,-244-5, July 28, 1914.)

**Pyrophoric Alloy.**—Mr. **Paul Faehr**, of the Elektrochemische Werke, Bitterfeld, Germany, patents "a metal alloy containing a metal of the rare earth group and one or more of the metals zinc, cadmirum, tin or lead in such proportions as to make the alloy pyrophoric" (claim 1). Examples are 40 per cent. cadmium and 60 cerium; 30 zinc and 70 cerium; 30 tin and 70 ncerium; 30 lead and 70 cerium; 10 zinc, 10 tin, 10 lead, 70 cerium. These alloys not only keep for an indefinite time when exposed to air, but also in the presence of moisture, neither are they affected by great changes of temperature, nor by being placed in water. (1,102,575, July 7, 1914.)

### Metallurgical Furnaces

**Sinter-Roasting Furnaces.**—In the type of sinter-roasting machines devised by Dwight & Lloyd, the material to be sintered is deposited from a stationary hopper onto a moving grate that passes over a wind box. Ignition of the charge is started by a stationary source of heat and continued to completion by a downdraft of air. In a patent granted to Mr. **Francis D. Weeks**, and assigned by him to the Dwight & Lloyd Sintering Co., of New York City, the above order of operations is reversed, in that the grate and the charge of sintering ore are stationary, while the feed hopper, igniter and means for removing the sintered charge travel over the grate. The idea may be applied to either annular or straight-line machines. The advantages claimed for this modification of the process are that the charge of material on the grate is not disturbed in any manner, and less tax is placed on the machine in moving the weight of ore and grate. (13,758, Reissued June 23, 1914.)

**An improvement in pot-roasting methods** is patented by **Josef Savelsberg**, of Papenburg-on-the-Ems, Germany, whereby the usual formation of a layer of fine material at the top of the charge is prevented. Steam is added to the air blown through the charge, in sufficient quantity to condense in the upper cold layers, thereby moistening the mixture and preventing a separation of the material to be sintered from the parts of fuel. Part of the steam also is decomposed by the glowing fuel, forming water gas and promoting the sintering operation. (1,103,318, July 14, 1914.)

**Grates for pan-roasters** form the subject of a patent granted to **John E. Greenawalt**, of Denver, Colo. According to the improved construction the grate is made of interlocking sections, instead of one piece, and provision is made for expansion of the units when subjected to the heat of the sintering operation. (1,098,-035, May 26, 1914.)

**Another improvement in pan-roasters** patented by Mr. **Greenawalt** consists in constructing the furnace in two sections, the lower one being the hearth and the upper the ignition chamber. These are made separable, and the upper portion can be transferred from one lower portion to another, thereby serving for the ignition of a number of charges on as many hearths. (1,103,196, July 14, 1914.)

**Electric heating of the air supplied to roasting furnaces**, such as the superposed hearth type, is disclosed in a patent granted to **Utley Wedge**, of Ardmore, Pa. It sometimes happens that air is not sufficiently heated by passage through the chambers provided between the hearths, and in order to supplement such heat the inventor proposes to construct electric heating chambers in the outer walls of the furnace, wherein resistance coils will insure the heating of the air to the proper temperature. (1,086,494, Feb. 10, 1914.)

## Temperature Control for Industrial Purposes

Many chemical, metallurgical and industrial processes depend upon the careful maintenance of the temperature at a certain predetermined point. Thermostats are appliances which perform this function automatically. There are quite a number of thermostats on the market which are very successful for temperatures up to the boiling point of water. But the requirements of many industries call for an instrument which can be used quite as successfully for much higher temperatures.

In the following article we give a description of the Geissinger thermostat which can be adjusted to practically any temperature (being restricted only by the choice of materials of construction), and which is therefore applicable to the widest range of industrial processes. Before we enter into a description of this particular instrument, a few general remarks on thermostat design and on the classification of the different types of thermostats may be useful.

In most applications of heat in manufacturing processes the process has to be guarded against too high a temperature. For this reason Mr. Geissinger points out that valves which will close automatically when they are deprived of operative power give a higher guarantee of safety than automatic valves which are held open by a spring against air pressure upon a flexible diaphragm. While electricity supply is subject to rare interruptions, yet such may happen, and valves which will cut off the heating process in case of such failure follow the "safety-first" principle.

As to electric power versus compressed air or hydraulic power for the operation of valves, Mr. Geissinger points out that after all in general industrial practice electricity is proving to be most reliable and tractable force at the command of the engineer. While the electricity supply may fail in rare cases, yet Mr. Geissinger thinks an air-compressor has more reason to "lay down."

As to mechanical details of construction Mr. Geissinger lays particular stress upon the effect of heat and age upon diaphragm-operated valves. Should heat and constant flexure produce a crack in the diaphragm the valve would open suddenly.

Any properly working temperature-control apparatus breeds confidence and causes relaxation of attention. For this reason reliability on the "safety-first" principle, as explained above, is all important. Another requirement of any temperature control for industrial purposes is that it should "work close and keep working." If the investment of automatic temperature control is worth while at all in a heating process, the control cannot be too accurate.

We may now briefly discuss details of designs of various types of thermostats. They may be classed into two main groups: (I) Thermostats which operate valves directly, without any supplementary power and (II) thermostats which direct the operation of the valves with the aid of a supplementary power supply.

Group (I) may be subdivided into two classes. In (Ia) we have valves operated by the direct expansion of rods. The fact that the expansion coefficient of the most expandable materials under 1 degree rise of temperature is small, and that this expansion must be sufficient to close and open the valve to its maximum requires that large dimensions be chosen for the expandable part, if close temperature control is desired.

As (Ib) may be classed those valves which are operated by the vapor tension of a liquid immersed in the material under control. The range of this type is limited by the boiling points of different fluids under reasonable pressure.

Group (II) in which a supplementary power supply is used and which comprises the majority of commercial instruments, may also be subdivided into two classes, according to whether (IIa) compressed air or water or (IIb) electricity is the auxiliary power supply.

(IIa) The instruments operated with compressed air (of a high coefficient of expansion) have expansion tubes of reasonable dimensions, called upon to open very small "leakage ports." This leakage operates a pneumatic relay, admitting air to close diaphragm-operated valves.

To the same class belongs the type making use of the vapor tensions of liquids in bulbs exposed to the material the temperature of which is to be controlled. Again, the motion of the diaphragm is limited to leakage control of the air supply to the diaphragm valve. The air ports are necessarily small and air-filters are an adjunct to these types of controllers, in order to prevent dust or oil (with which the air in manufacturing processes is often charged) from choking the fine air ports.

(IIb) In the electric thermostat class we find possibly both the oldest and latest forms of instruments.

We are all familiar with the compound bar made of plates of brass and steel riveted together. Such compound bar is fixed at one end and free to make contact on one or two points at the other end. The layers of metal must be made thin to produce a marked motion of the free end under changes of temperature. This same condition makes the whole structure a weak spring. This form of thermostat must be subject to several degrees change of temperature to create a small pressure between its contacts.

The effect of pressure on the contact resistance of two platinum contacts has been the subject of special investigation. Mr. Geissinger states he has found that an electric thermostat working under commercial conditions has to exert a pressure between the contacts of at least 0.01 lb. in order to close the circuit and that this pressure must probably be double with a trace of oil between the contacts.

Another modern type uses the vapor pressure of a volatile liquid, or the expansion of mercury in a bulb exposed to the material under control, operating the familiar pressure tubes of recording instruments, the index hand being equipped with one or two contact points. Mr. Geissinger states that "a mercury-filled temperature recorder-type thermostat with a pointer moving 0.3 in. for 10 degrees F. exerted a force of 0.02 lb. under restraint produced by a difference of 10 degrees F."

The sensitive portion of the Geissinger thermostat shown in the adjoining illustration consists of a metallic or vitreous tube with some coefficient of expansion, and an inner rod of an alloy of practically zero coefficient of expansion.

The tube is either cast integral with or welded to the head. The end of the tube is fused over.

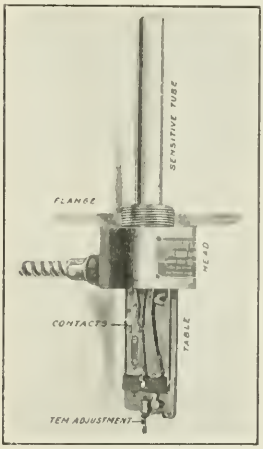
There is bolted to the head a part called the table, carrying the electrical parts of the instrument, the "contact" and the "contact arch." The inner end of the contact arch is operably connected to the non-expanding rod, while the outer end is held in a piece united to the inner end of the table by flexible side bars. The side bars and contact arch are of the same length, section, and material. They expand equally under any temperature the head may be.

The free end is capable of considerable lateral movement on the table, on account of the flexibility of the side bars. Such movement is produced by the temperature adjusting screw operating through an angle lever. Displacement of this free end alters the distance between the contacts. Each adjustment demands a different expansion length of the sensitive tube to produce contact and consequently another temperature in the surrounding medium.

The contact arch is a normally flat piece of spring steel, forced into a shallow arch by end pressure, or shortening of the chord. It is evident that the movement of the vertex of such an arch is a magnification of the shortening of the chord, the relative motion being a function of the length over the height of the vertex.

Again, imagine a non-compressible shallow arch set in an inelastic chord, loaded in the center. Such arch can be loaded without change of shape, until it "breaks" like masonry. In the action of the thermostat the vertex of the contact arch is brought against the contact point, and apart from the end thrust and compression of the parts, instantaneously a force is obtained which "breaks" the arch into a curve with three radii. The pressure between the contacts after the "break" is 0.6 of the breaking load.

Now for any size and material the breaking force is proportional to the height of the vertex, and the longitudinal stresses uniform in all heights of vertex. It should be borne in mind that we have to do with curves with relatively long radii.



ELECTRIC THERMOSTAT

The rigidity of the contact mechanism permits the use of sensitive tubes of a very low coefficient of expansion, covering a wide choice of compositions appropriate to the temperature and chemical nature of the material under control.

The maximum contact pressures are variously set between 0.75 and 2 lbs. No matter how great the difference between the working and atmospheric temperature, the contact pressure when cold is 60% of the maximum. The compressive stresses are negligible, there is no "set" to the tube. If an instrument cools off once a week it keeps clean of oxide. If in fact anything interfered with the passage of the current between the contacts, it is at once crushed by a force that amounts to 0.9 lb. per deg. F. below the standard temperature. This comparatively very high force ensures the reliable working of the instrument.

The Geissinger thermostat is made by the Geissinger Regulator Company, 203 Greenwich Street, New York.

**Borax.**—In 1913 the production of crude borate materials in the United States was 58,051 short tons valued at $1,491,530, according to the U. S. Geol. Survey.

# Repairing a Crank Shaft by Autogenous Welding

BY C. H. BURROWS

A chief engineer is frequently required to use unerring judgment in making extensive repairs in his power plant, and to make these repairs permanently durable and neat in appearance in a quick and economical way. An occasion which requires such ability comes unexpectedly and is usually attended by a complete shutdown of his plant. To keep himself forearmed for these emergencies, it is desirable to know of the methods and success other mechanics have had under such circumstances; and with a motive to contribute to his preparedness, I call attention to the prompt results and unusual success obtained in repairing a large crank shaft by autogenous welding with an oxy-acetylene torch.

The crank shaft was 6 in. in diameter by 11 ft. long, and was a member in a three-cylinder 100-hp producer-gas engine belonging to a single-unit electric-lighting plant.

It was broken square off through one of the arms and totally disabled the entire plant.

Just previous to the welding operation, the fractured ends were placed in a glowing bed of charcoal, and surrounded by brick to thoroughly preheat the portion adjacent to the fracture. This performance was not vital to the actual welding operation, but was only an economic measure to save gas. After preheating it was perfectly aligned on V blocks and with the torch a gap was cut on opposite sides. The sloping sides of the gap forming an angle of about 75 deg. with the vortex at the point of fracture, in the center of the shaft. This cutting was done entirely with the torch and left the sides of the gap dripping with molten metal, which condition penetrated the material of the shaft. In fact, it would be exceedingly difficult to determine just where this molten condition actually terminated. This fluid and semi-fluid state was maintained or renewed with the torch while the gap was being welded full of molten steel from the welding rod, working from the center of the shaft outward.

The weld was then finished by eventually melting away the superfluous metal and smoothing off with the torch. The apparatus and the torch used were those furnished by the Vulcan Process Company, of Minneapolis.

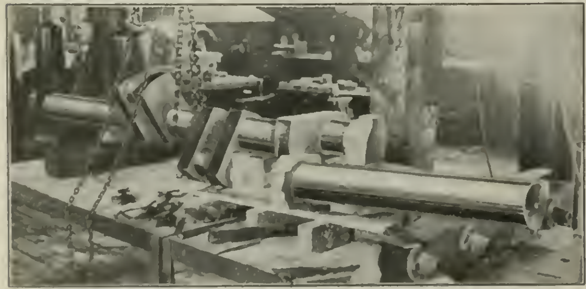


FIG. 1—CRANK SHAFT BROKEN

The complete job was welded and ready to deliver in less than twenty-four hours at a cost of about $26 as

| | |
|---|---|
| 8 hours welding time at 35c | $2.80 |
| 812 cu. ft. oxygen gas | 16.24 |
| 817 cu. ft. acetylene gas | 6.54 |
| 50 lb. charcoal at 1c | .50 |
| | $26.08 |

After cooling the weld was found to be perfectly homogeneous in texture, void of fire-scale or oxidation, and machined freely.

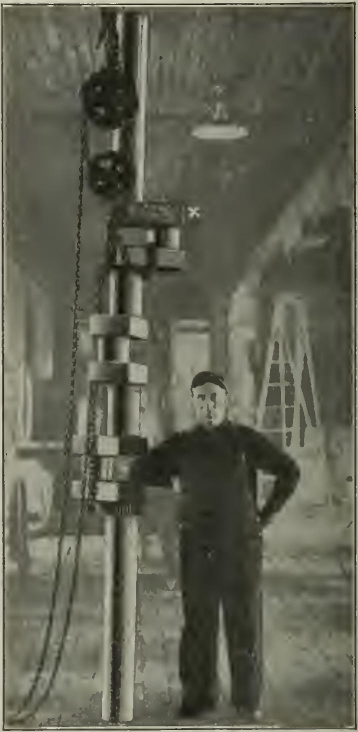

FIG. 2—CRANK SHAFT WELDED

This crank shaft has now been in heavy service for several months and given perfect satisfaction.

Minneapolis, Minn.

---

## Recording Gas Calorimeter

Primarily for use in gas power installations the Lexington Instrument Works, of Lexington, Ohio, has developed the Smith recording gas calorimeter which is perfectly automatic in giving the heat value of a gas (for instance, producer gas) per cubic meter. The record of the instrument is automatically corrected to the accepted standard of gas at 60 deg. Fahr. and 30 in. barometer. The readings are also practically independent of atmospheric conditions.

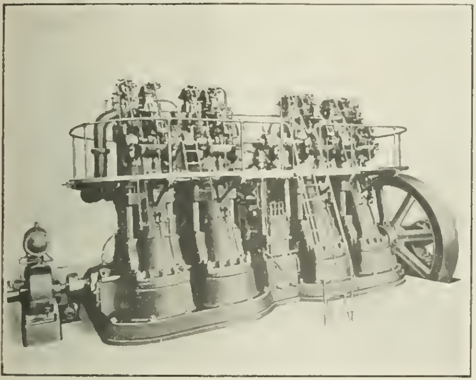
The equipment consists essentially of two parts, namely, the sampling pump and the calorimeter. The sampling pump is a small power-driven metering apparatus, which delivers continuously a measured and proportionate amount of gas and of ordinary atmospheric air. The gas and air are delivered from the sampling pump through separate pipes to the calorimeter, where the gas is burned in and with the air and the rise in temperature of the air recorded as a measure of the heat value of the gas.

The instrument is designed primarily for use in gas-power installations, to control the effectiveness of the gas for operation of the gas engine and also to control the efficient working of the gas producer. It may also be employed to advantage where gas is to be used for metallurgical purposes requiring fine temperature adjustments.

## Large Oil Engine

The largest Diesel engine ever constructed in America will be the first piece of heavy machinery of this type taken through the Panama Canal.

The engine is composed of four huge cylinders and is capable of developing 690 horse-power. It was constructed in the immense plant of the Lyons Atlas Company of Indianapolis and has been sold to the Hawaiian Commercial & Sugar Company to be used for irrigation purposes in the Hawaiian Islands where it will operate pumps of 15,000,000-gal. capacity.



LYONS-ATLAS DIESEL ENGINE FOUR-CYLINDER, 600-660 BHP ENGINE WITH DIRECT-CURRENT-CONNECTED AIR COMPRESSOR

The big Diesel engine left the Indianapolis factory last month for Hawaii via the Panama Canal.

The conditions covering the acceptance of the engine were severe. The purchaser insisted that the engine should operate continuously 710 hours out of each 720 hours per month at rated load, using the ordinary 14° to 18° asphaltum base California fuel oil, similar to that used in the purchaser's steam plant, and which is the only grade available on the Islands.

The test was conducted by the chief engineer of the H. C. & S. Co., and the engine was given a preliminary continuous run of forty-eight hours with Eastern parafine base fuel, after which all parts connected with the combustion chambers were inspected in order to determine a basis for comparison between the effect of the two fuels. It was then subjected to a 144-hour continuous run at full load with fuel shipped by the purchaser from California to the manufacturer's works. At the completion of this run the combustion chambers were again examined, and as there was no evidence of deposit on the heads, valves or pistons, the engine was accepted and is now en route to the Island, to be erected by their own engineers.

---

The **Fuller-Lehigh Pulverizer Mill** is the fifth of a well-illustrated pamphlet, issued by the Lehigh Car, Wheel & Axle Works, of Fullerton, Pa. It is particularly interesting on account of descriptions of equipment used for the production of pulverized coal suitable for heating industrial furnaces.

## American Manufacturers and the European War

In reply to a request for an expression of opinion a to the effect of the war on metallurgical and chemical activity and on business in general, *Metallurgical and Chemical Engineering* has received numerous statements from American manufacturers.

Manufacturers of machinery for the non-ferrous metallurgical field refer to the cutting in half of the activity in copper smelters and refineries. One prominent manufacturer writes: "The effect of the war on our business has been that copper inquiries have stopped. One of our best orders has been canceled, and another was attempted to be canceled, but was already shipped."

Among the replies from steel manufacturers the following is typical: "We import from Europe ferromanganese and magnesite, but no alarming shortage of these materials has developed so far and we think the steel manufacturers will be able to secure all they will require, although probably at somewhat higher prices. This, of course, will have the effect of increasing the cost of steel making.

"The effect of the European war on our own business has been to curtail it and we look for somewhat decreased operations during the remainder of the year. This has been brought about by the inability to finance new enterprises, new buildings and the railroads. Spelter, of which we are large users, has advanced in price, owing to the alleged large demand from England, which, however, has only materialized in comparatively small tonnages. Spelter is in abundant supply in this country and will probably reach a normal price level within a few weeks."

Another manufacturer writes: "In the event of the supply of ferromanganese either being exhausted or the price becoming very high, ferrotitanium would undoubtedly be substituted therefor to a considerable extent so far as ferromanganese as a deoxidizer is concerned. In some instances, where titanium is being used, manufacturers have cut down to a certain extent the amount of manganese in their steel, although it is not wise to recommend such a change at this time."

The *Noble Electric Steel Company*, of San Francisco, Cal., states that anticipating the present conditions it has recently been preparing to manufacture ferromanganese at its electric smelter at Heroult on the Pit, and within the next ten days one furnace will be blown in, with the possibility of a second furnace being blown in a few days later. In California there are a great many manganese deposits, several of which are of considerable extent and of good grade, but inability to meet foreign transportation costs has caused these properties to remain idle. Now the Noble Electric Steel Company can enter the field of making ferroalloys of manganese and chromium. It will not be slow to take advantage of the opportunity the European war has created. The furnaces at Heroult are admirably adapted for the purpose, as metallurgical details for making ferromanganese are quite similar to those in making pig iron. The Noble Electric Steel Company expect to get a market for its ferromanganese not only in the steel works on the Pacific Coast, but also in Japan.

Mr. Wm. C. Cuntz, general manager and treasurer of the *Goldschmidt Thermit Company*, of New York City, says: "I do not see that our business will be affected by the war, other than in the general effect the war will have on all business. We are in position to manufacture practically all our material here and while certain raw materials are difficult to get and high priced at the present time, I am inclined to think that this situation will soon straighten out, provided some way is found of putting the business of the country in the hands of business men rather than those of politicians, and provided also that economy is practised by these same politicians and everyone generally. By economy I mean not only in personal matters, but in the treatment of resources."

A prominent manufacturer of platinum ware states that "so far the effect of the European war has been to increase the cost by from 10 to 15 per cent, this being in part largely due to the increase in cost of transportation, insurance, war risk and exchange. For the present we have sufficient stock in hand to meet our customers' reasonable requirements, and as to the future a great deal would depend upon the duration of this trouble, for, as is probably well known, Russia is the chief source of supply. As to a substitute, the peculiar and noble qualities of platinum preclude the possibility of using a substitute in a great many instances or uses, and in this connection we might state that in some lines where they have attempted to use a substitute they have been forced to return to platinum. As yet we are unable to say anything definite as to the possibilities of South American trade."

Among electrochemical manufacturers, Mr. W. Acheson Smith, general manager of the *International Acheson Graphite Company,* states that its "supply of raw materials has not been interfered with in the least, and we are prepared to supply Acheson graphite in any quantity."

An electric-furnace operator states that the only supply he has been obtaining from Europe has been large carbon electrodes. "As these are now also made in this country we do not feel that the European war will affect us seriously in any way in manufacturing."

Mr. C. L. Allen, general manager of the *Norton Company,* Worcester, Mass., states: "We are not dependent upon European raw materials. We have received from time to time a few raw materials from Europe, but have never been dependent upon them. Whatever we require is available in this country. We are not looking for substitutes. As more or less abrasives have been imported it is possible that we may be able to supply some of our own in place of these. So far as our line is concerned the effect on export business ought to be favorable, but not now to a great extent because the demand for our goods is not fully developed."

Mr. Geo. E. Long, vice-president of the *Joseph Dixon Crucible Company,* states: "We have been dependent on Germany for clay for crucible making and for the clay which enters into pencil making. We would gladly have used an American clay if one could have been found suitable. So far none has been found. It is not a question of price but of material only. The Dixon company has also been obliged to look to Germany for its best quality of mineral colors and aniline colors. We are looking now, as we always have been, for these materials in our own country, and there are no substitutes so far that we have been able to find."

Activity in certain chemical fields is indicated in various replies from manufacturers of chemical apparatus and machinery, although several of them do not wish to be quoted for publication.

Messrs. *L. O. Koren & Brother,* of New York City, write as follows: "Very soon after hostilities commenced between the nations at war in Europe we received inquiries from a number of both large and small producers of chemicals for special apparatus, same to be used in the manufacturing of chemicals which until now, we understood, were manufactured abroad. In some instances chemicals, for which we have orders for special apparatus, were being manufactured here in some quantities, but as the foreign supply has been lessened it will be necessary to increase the output for such chemicals here very materially. In some cases chemicals which were not manufactured in the United States in the past are now, so we are advised, being made here. As a result of the increased production of chemicals in the United States we have received orders in the past few weeks for apparatus which we believe would not have been ordered of us had the conditions in Europe not changed. Some of the apparatus which we are making are duplications of what we made heretofore. We also contemplate the building of apparatus which will be duplicates of things now used abroad. . . . We believe that the manufacture of any chemical products which are once manufactured in this country will be continued. This has been the case in the metal lines. After the factories are once provided with the necessary equipment and the men familiar with the methods of manufacture, there is no reason why chemicals once manufactured here should not be made in competition with foreign goods."

Mr. F. J. Stokes, of the *F. J. Stokes Machine Company,* Philadelphia, states that his company is in nowise dependent on Europe for materials, but as its sales are mainly to the manufacturers of chemicals and pharmaceutical preparations, who have been seriously affected, sales have been slightly influenced. "Pharmaceutical manufacturers have been enjoying a sudden rush of business, which seems to be regarded by them as only temporary and, therefore, they will not purchase additional equipment. The same applies to the manufacturers of chemicals, although there is a disposition on their part to take up the manufacture of the products heretofore imported. The installation of new apparatus of this kind requires careful consideration and the increase of sales from this source will not be immediate.

"In reference to exports to South America, there has been an increase in requests for quotations. South Americans, however, are slow buyers, especially in apparatus of a technical nature, and considerable correspondence has to be entered into before they will place an order. We do not, therefore, look for much increase from them under two to four months."

Mr. F. M. de Beers, general manager of the *Swenson Evaporator Company,* of Chicago, Ill., believes that "the final result of the war, so far as American manufacture is concerned, is bound to be beneficial and that it will open up new fields of endeavor. So far as our particular business is concerned it will help us by eliminating some price competition in foreign countries, which resulted in so much of the business going to European manufacturers. As regards the purchasing of evaporators to be used in the United States, or in our neighboring countries, the war can hardly affect this one way or the other, as the best machines are built here, and the American purchaser knows enough to disregard a possible lower price of a foreign competitor. There is no immediate effect upon our costs, as most of our raw materials are produced here, but the financial condition is such that most new and large developments in the chemical industry are being postponed or abandoned."

Mr. R. L. Cawood, manager of the *Patterson Foundry & Machine Company,* of East Liverpool, Ohio, states that "we have hardly had sufficient time in which to judge what European conditions will do for America or what effect their troubles are going to have on our industrial condition. Theoretically, at least, their misfortune should be our opportunity. This should improve our export business to South America, as this country is now the logical source of supply for that territory and a great many of our products should find a ready market there.

"So far as importations of material into this country are concerned, I believe that this will temporarily work a hardship on a few manufacturers who are importing materials that are not at present made in this country. This handicap will gradually disappear as substitutes for these materials will undoubtedly be found in this country and similar materials manufactured here. This will mean increased industrial activity throughout this country. Goods like pottery, toys and other articles which are imported very extensively and which are no better than similar articles made in this country, will be made here in place of being imported. Two-fifths, or in other words 40 per cent, of our china and earthenware is imported. It is no better than the home product, but is made with cheaper labor abroad. The importation of these goods being shut off will undoubtedly help our own manufacturers.

"The stocks of imported goods in this country at the time of the European outburst were sufficiently large to tide over a great many consumers until the present time. Consequently we have not as yet felt the real effects of the changed conditions. In my opinion it will be sixty days more before we do so."

Another Middle Western manufacturer of machinery for chemical and allied industries, who wants to remain unnamed, says that "so far the effect of the war upon our business has seemed to be a quite general deferment of anticipated requirements. Our opinion is that the cutting off of certain supplies from Europe will result in a slow-up until other sources of supply or substitutes can be obtained or peace permits a resumption of deliveries. We believe the effect upon export business will be a curtailment until the war closes. It will take much time, careful, direct investigation and adjustment to ways and means that are not attractive but can, no doubt, be harmonized to mutual advantage if both interests pursue the policy of give and take."

The vice-president of a prominent Eastern manufacturing company, desiring to remain anonymous, writes: "A very large proportion of our business is with the railroads and while they are, as we all know, suffering from lack of supplies and equipment, they are not buying anything that they can possibly do without; nor do we see how they will be in a position to buy normally until there is some financial readjustment effected that will enable them to borrow money freely.

"We do considerable business with some of the larger industrial plants, one or two of which have held up a great many orders owing to the general financial situation. As far as we can see, this is more a measure of precaution than of necessity, however.

"We do not feel that the export business to South America will be of such a volume as is popularly supposed until this country is in a position to help them finance their operations. It is our observation that most of the South American countries are at present in financial straits, owing entirely to the European war and the manufacturers in this country are in no position at the present time to grant the long credits that have been customary with the English and German manufacturers on South American business.

"We believe that the railroads will eventually secure their 5 per cent increase and that the financial situation will slowly adjust itself to the new conditions, and that shortly after the first of the year business in general will return to a more normal basis.

"We feel, however, that it is going to be some time before the American manufacturers and foreign buyers can so rearrange their methods of buying and selling that any greatly increased export business will result. However, we feel that this business is bound to come in time, and that when the South American countries are once educated to the purchase of goods from this country that Europe will never recover the business."

The *American Vulcanized Fiber Co.*, of Wilmington, Del., makes the following statement:

"The raw materials from which vulcanized fiber is made, viz., cotton cellulose, coloring matter and zinc chloride, are all imported into this country in very large quantities. The European war has, of course, stopped the importation of these commodities, with the result that the cost of all our raw materials is steadily increasing. Unfortunately, no substitution can be made without more or less seriously impairing the quality of the finished product.

"For instance, cotton cellulose in the form of rags costs now $10 to $20 per ton more than a month ago. We have our own mill which separates directly from the cotton hulls a very pure cellulose which we use largely for certain grades of vulcanized fiber, but we also use large amounts of cotton cellulose in the form of rags, the price of which in this country is regulated by the European supply.

"It is at present almost impossible to get aniline colors, and manufacturers of fiber in common with many others will be forced to depend entirely upon mineral pigments, with the inevitable result that the price of these will be forced up. Certain colors will probably have to be discontinued after the supply of coloring matter now on hand runs out.

"The price of zinc chloride and even the available supply is likely to be seriously affected by the war, as is seen by the fact that large quantities were imported from England and Germany in 1913. We ourselves are somewhat more fortunate than most, because we have an independent source of supply for zinc chloride which will not be affected by European conditions. In this connection we are glad to state we shall have during the next twelve months an excess of this chemical, which we can deliver in our own tank cars as a C.P. or commercial solution of any desired strength. We also have our own supply of pure red oxide pigment, and expect to be able to offer some of this for sale.

"The immediate effect of the war is to reduce very materially domestic sales of our finished product. In our opinion the ultimate effect of the present war may be to stimulate the export business with countries other than Europe, but it is not to be expected that this will make up for the loss of the European trade, for industries in those countries have not developed along lines that require vulcanized fiber in the large quantities that are used abroad, and we are, of course, in general adjusting our organization to meet the changed conditions."

Mr. F. R. Still, secretary of the *American Blower Company*, of Detroit, Mich., thinks that in spite of some discouraging indications "there is every reason for believing that business should be good, and it will it everybody will keep cool and proceed cautiously and steadily. It will take some time to adjust finances to the changed conditions and still longer before business gets up the momentum to meet the coming demand, during which period expenses and credits must be watched carefully. 'Necessity is the mother of invention'; this war will be an incentive to find substitutes for many materials we all have been accustomed to use, or to induce capital to invest in the production of old material heretofore produced in Europe almost exclusively. The final result will probably be much the same as was the building up of the tin plate industry under the McKinley tariff; when capital was offered the inducement it went into it and soon got onto a footing that almost excluded foreign competition.

"Our company has been dependent on the European countries for raw material only in a limited degree, such as tin, manganese, plumbago, etc.

"South America is reported to us to be in a bad way financially and business is almost at a standstill. If our Southern neighbors can place large loans in this country, and branch banks be established down there and capable representatives be sent to canvass their wants, and goods be made to suit their demands, then a big business should ultimately be the fruits of such efforts, but this is a long time away and with characteristic American impulsiveness, many are likely to become discouraged in their efforts before the successful conclusion of such a campaign is reached. If the war lasts long enough to enable this country to get started in foreign fields, Europe can never overtake us in this or the next generation. But should it suddenly cease, in the near future, we will find ourselves just where we were before it started."

Mr. W. F. Graver, vice-president of the *Wm. Graver Tank Works*, of East Chicago, Ind., states that they "have been selling storage tanks to some of the refiners who export petroleum products to the European countries, and this business is necessarily curtailed until the existing conditions abroad are changed. On the other hand, the curtailment of petroleum shipments has increased the need for storage in this country and some of the larger companies are buying considerable tankage to take care of the production.

"As to the effect on export business, I would say that benefits must necessarily accrue as far as the steel line is concerned as the greater part of material in this line for South America, the Islands and Mexico are shipped from Germany. As far as our line is concerned, our experience would indicate that a large amount of export businss is lost annually through indifference and unfamiliarity with foreign requirements and conditions. We believe that, once established, our trade with South America will be permanent.

"We also believe that the existing conditions will convince the American manufacturer of the undesirability of being entirely dependent upon foreign countries for raw material and that they will not overlook the opportunity to develop industries which are now perfected abroad, and to draw on our vast resources for substitutes to replace foreign produced raw materials now unavailable. These changes must eventually come and the present state of affairs makes it imperative that the changes come now."

Mr. Irving C. Jennings, manager of the *Nash Engineering Company*, of South Norwalk, Conn., states that "business fell off somewhat with the start of the war, but is now picking up again."

Mr. *A. J. Weeks*, manufacturer, of Akron, Ohio, states that they have everything they need for manufacturing chemical stoneware in Ohio, so that they are affected by the war only as far as the general business is affected. "The tariff revision did hurt, as it placed foreign ware on less duties into this country. This war may help us somewhat in the near future, cutting off foreign importations. It will take time and facilities to get into exporting to South America. In the end I consider the war will not be of great benefit to this country as calamities usually spread and affect all the conditions of the world."

Mr. *Maurice A. Knight*, of East Akron, Ohio, states: "As Germany imported a good deal of acid-proof stoneware, we now expect to get our share of what was their business. Our ability and equipment to get out our product has not been affected in any way. I have had more inquiries from South America in the last six weeks than ever before."

Mr. F. E. Finch, of the *Ruggles-Coles Engineering Company*, of New York City, staes that they have had several orders canceled, especially for foreign shipments, due to the present war, but have also received inquiries and orders from companies and individuals who would usually go to France or Germany for their machinery. "We expect to increase export business to South America, and hope to place that on a firm foundation."

The manufacturer of a chemical commodity which is largely used in the electrical industries, writes: "The volume of our business would be almost entirely dependent upon the prosperity of the general electrical manufacturing industry of this country. How this is to be effected by the present European situation is more than the writer can vouchsafe to answer.

"We have not reduced or increased our organization recently, although our business continues to maintain itself in a very healthy condition. We have so far been almost entirely dependent upon Europe for certain supplies, but it is the writer's opinion that if the interruption to European manufacture and export continues for any length of time the coke producers of this country will desist from wasting their by-products."

The president of a company making special electrical machinery who likewise wishes to remain anonymous, states: "Up to the present time we have not been seriously inconvenienced by being cut off from European raw material. Very little of such materials have entered into our devices and we were fortunately well provided with such minor items as solder, etc., which do not enter in large quantities into the construction of our apparatus. Simultaneously with the outbreak of the war there was, and still continues to be, a marked increase in business, and we have traced a number of these orders to electrochemical and electrometallurgical organizations which will endeavor to supply materials which have formerly been coming from abroad. Our bulk of business on hand at the present time exceeds that which we had on hand a year ago. We do not look for any great increase in orders for special transformers from the South American trade, but will expect to profit indirectly from the business which the electrochemical and electrometallurgical industry of this country will undoubtedly secure."

Messrs. *Merck & Company*, of New York City, have issued an Emergency Price Guide for temporary service. One strong recommendation made in it is to use sodium salts instead of potassium salts wherever possible. "The sodium salts, of which there need be no more than a temporary lack, deserve to be more widely issued, and we would urge all our friends to use them in all cases where they have been in the habit of using the potassium salts, because of the constant source of supply."

Mr. Chester G. Fisher, vice-president and general manager of the *Scientific Materials Company*, of Pittsburgh, Pa., says: "A large portion of our chemical apparatus has been made in Europe. The principal reason for making many of these articles in Europe is not because they could not be made in this country, but because they could be made in Europe considerably cheaper. We are at present manufacturing many articles here in Pittsburgh which we have heretofore made abroad, but the cost of these articles is considerably greater than the same articles made in Europe. There are, of course, some articles which have been developed to a very high degree in Europe which would take a long time and considerable research work to equal were we to make them in this country, and on such articles we have no recourse but to wait until the European situation adjusts itself."

A pyrometer manufacturer who wants to remain anonymous states that he has been importing considerable raw material from Europe and when his supply runs out he expects some difficulty in obtaining them. The war has also affected his export business to Spain, Sweden and other countries.

Mr. C. H. Wilson, of the *Wilson-Maeulen Company*, of New York City, writes: "As most of our importations are from England, these have not been materially disturbed. There are some few things which we have obtained from the Continent which we can unquestionably replace from local sources. In this connection it seems that someone should point out to the American manufacturer that when someone comes to him to replace what that someone has been heretofore obtaining from Europe, the American manufacturer should take a keen interest in the prices and qualities of what has heretofore been imported, otherwise the American manufacturer can hardly be very sure that he will hold the trade when European business gets back somewhere near the normal. That is to say, even if he finds his customer willing to accept what he has to offer, he should bear in mind that that customer may be accepting it as a temporary shift and that this is the time when he should display such keen interest in the requirements of his customer and should expend such efforts to meet the requirements as will insure permanently holding the business."

## Personal

Mr. **Franklin Guiterman** spent the month of September at the Denver office of the American Smelting & Refining Co. Mr. **L. G. Eakins**, manager of the Colorado department of the company, was absent on vacation.

Mr. **Stuart S. Bruce** has resigned his position as professor of metallurgy at the Michigan College of Mines, and will be out of professional work for a time. At present he is at Victoria, B. C.

Mr. **W. J. Pentland**, manager of the Amajac Mines Co., has returned to Mexico and will make an effort to renew the work of constructing a cyanide mill. He will be at Hotel Cosmopolita, Guadalajara, Jalisco, for a time before going on to Hostotipaquillo.

Mr. **J. B. Tregloan**, superintendent of the McNamara mill, Tonopah, Nevada, has returned to his duties after an extended trip east.

Mr. **D. L. H. Forbes** has been appointed chief engineer of construction for the Chile Exploration Co., and has gone to Chuquicamata. He was formerly on the staff of the Merrill Metallurgical Co., and consulting engineer for the Trethewey mine at Cobalt.

Mr. **W. P. Lass**, superintendent of the cyanide plant of the Alaska-Treadwell Gold Mining Co., resigned his position, effective Sept. 1. He will open an office in Juneau with Mr. **E. P. Kennedy** and give attention to the development of the Speel river hydro-electric power project.

Mr. **Frederick Lyon**, vice-president in charge of operation for the U. S. Smelting, Refining and Mining Co., is making a tour of the company's plants in California, Arizona, Indiana and New Jersey.

Mr. **C. B. Lakenan** is reported to be recovering satisfactorily from an operation recently performed at the Mayo hospital.

Mr. **Andrew W. Newberry** visited Utah and Colorado mining districts following the Salt Lake meeting of the American Institute of Mining Engineers.

Mr. **William W. Clark** has resigned as chief chemist and metallurgist of the American Vanadium Company to accept a position as metallurgist with the Seymour Manufacturing Company, which will install a metallurgical laboratory.

Prof. **Joseph W. Richards**, of Lehigh University, has returned from Europe via Copenhagen. He was in Germany when the war started.

## Obituary

**James Porter Evans** died suddenly at his home, 1427 Franklin St., Denver, Col., on Sunday evening, September 13.

Born at Zanesville, Ohio, November 29, 1860, he came to Denver in 1881 and engaged in the railroad business. He continued in that field, rising through various positions to that of auditor of the Denver and Rio Grande Express, which connection he severed in 1895 to enter the Colorado Iron Works Co. of which he was vice-president and general manager at the time of his death.

His activities in connection with the development and manufacture of mining and smelting machinery brought him into intimate contact with many men of note, and in his sudden demise the mining industry loses a prominent figure.

Mr. Evans had drawn to himself a wide circle of friends who had become endeared to him through his upright character and genial disposition. Upon these his loss will fall as a personal bereavement. He had long suffered from asthma and the fortitude with which he bore up under repeated severe attacks of this ailment was a source of admiration by his intimate friends. Taken with pneumonia on Wednesday but few knew of his illness and none feared its fatal termination. He belonged to Oriental Lodge No. 87, A. F. & A. M., of which he was a charter member, Denver Commandery No. 25, Knights Templar, and of El Jebel Temple, A. A. O. N. M. S. He was also a member of the American Institute of Mining Engineers, the Denver Club and the Denver Country Club.

He is survived by his widow, Mrs. Isabel Nesmith Evans and one daughter, Elisebeth.

## Digest of Electrochemical U. S. Patents

PRIOR TO 1903

*Arranged according to subject-matter and in chronological order.*

*Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.*

AQUEOUS BATH (ELECTROPLATING) *Continued*

570,554, Nov. 3, 1896, Eduard Jordis, of Munich, Germany.

Relates to the art of electrodepositing metals or alloys, and also to scouring or cleaning by electrolysis, and consists in the employment of lactic acid or lactates in the bath. When employing pure solutions of the required metal lactate, such metals as nickel, iron, copper, and zinc are deposited and have a dark velvety color. By the addition to the electrolyte of alkaline lactate, and sulfates or other salts of more electropositive metals than the metal to be deposited, such as aluminium, magnesium, etc., the color of the deposited metal will be lighter, so that many shades of deposited metal may be contained, by adjusting the conditions of concentration, temperature, and current density. The conditions for electrodepositing several metals are given.

571,531, Nov. 17, 1896, Rudolf Langhans, of Berlin, Germany.

Relates to the electrolytic production of oxide coatings of the earth and alkaline earth metals. To a solution of a salt of an earth or alkaline earth metal is added the hydroxide of the same or different base, and dissolved therein with the aid of heat; the resulting solution is electrolyzed with insoluble electrodes, with high or low current density, a deposit of a hydrated oxide separates out and adheres more or less closely to the negative electrode according to the condition of the electrolyte and the circumstances of the electrolysis. The conditions are given for obtaining deposits of the hydrated oxides of zirconium, thorium, yttrium, aluminium, and magnesium; and for obtaining an oxide deposit upon a wire mesh incandescent gas-light mantle.

571,532, Nov. 17, 1896, Rudolf Langhans, of Berlin, Germany.

Relates to the electrolytic production of oxide coatings of the earth or alkaline-earth metals which will be porous and both cohesive and adhesive. Aqueous solutions of the water soluble or "meta" hydroxides of the earth or alkali-earth metals are well adapted for this use. A diluted solution is employed, containing about 3 per cent, for example, of the water-soluble hydroxide of thorium, and electrolyzed with a current of 0.03 amp per sq. cm. The deposit is a perfectly cohesive and adhesive layer of insoluble hydroxide, which may be calcined to the oxide without loss of these properties. The soluble hydroxide can be prepared as follows: oxide of thorium obtained by ignition of the oxalate is heated with excess of nitric acid, or hydrochloric acid. When the excess of acid is expelled by heating in a water-bath a residue is obtained which is soluble in water.

The patent refers to a co-pending application which became patent 571,531.

571,533, Nov. 17, 1896, Rudolf Langhans, of Berlin, Germany.

Relates to the conversion of precipitated hydroxides, such as described in patents 571,531 and 571,532, into insoluble or difficultly soluble salts, which are easily converted into oxides by heat. The electrode on which the hydroxide is precipitated is connected as an anode, to a weak source of electricity, and placed in a solution containing, for example, selenious acid, tartaric, oxalic, formic, tannic, or carbonic acid; the current immediately transforms the hydroxide into the corresponding salt or salts. The coated body is next removed, washed and calcined.

598,313, Feb. 1, 1889, Ernest P. Clark, of New York, N. Y., assignor of one-half to Charles S. Campbell, of same place.

Relates to depositing lead in a "feathery' finely divided condition. A solution is made by adding 1 lb. 10 oz. of acetate of lead to each gallon of water, the excess of acetate not dissolving being suspended in a coarse cotton bag near the top of the solution. The lead is precipitated as a frothy deposit by clean metallic zinc, the excess of lead acetate dissolving as lead is precipitated, the precipitation being stopped when the solution reaches a specific gravity of 18 or 19 deg. Baumé. The solution will now have a light-brown color.

Upon then inserting a lead anode and lead cathode, and passing a current, a deposit will appear which may at first consist of bright crystals of metallic lead, or a frothy deposit. After some time a feathery deposit will appear; the other deposited lead is then entirely removed from the solution, and deposition continued. After some time the brown color disappears, and the solution becomes entirely clear. The feathery deposit is said to be useful in making accumulator plates. It is stated that a deposit of this character cannot be produced by mixed solutions of zinc acetate and lead acetate.

602,872, April 26, 1898, Joseph W. Richards and Charles W. Roepper, of Bethlehem, Pa.

Relates to producing compounds by electrolysis with an alternating current. An application of the process is as follows: on immersing an anode and a cathode of cadmium in a solution containing 10 per cent of sodium hyposulfite and passing either a frequently reversed current, or an alternating current, sulfite of cadmium will appear as an insoluble coating on each electrode, the hydrogen evolved at the electrodes on reversal, mechanically disengaging the sulfide, which falls to the bottom of the vessel, and keeps the electrodes clean.

607,484, July 19, 1898, Josef Rieder, of Munich, Germany.

Relates to obtaining reliefs in metal by electrolysis for dies, etc., and consists in first making an impression of the relief on a porous block of plaster of paris, etc., or in engraving the same upon a suitable porous stone, saturating the porous block with an electrolyte that will dissolve the metal to be etched, placing the metal to be etched on the impressed or engraved side of the stone, connecting it as anode, and a suitable cathode on the other side of the stone. On passing a current, the anode is dissolved only at the points of contact with the stone, the pressure of the plate against the stone maintaining contact. The plate is eventually dissolved off so as to produce an exact counterpart of the impression in the stone.

A modification shows the lower part of the stone and the cathode immersed in an electrolyte.

## Book Reviews

**Chemical Analysis of Special Steels.** By **Dr. Charles M. Johnson.** Second Edition, rewritten. 438 pages, 39 illus. Price, $3.00. New York: John Wiley & Sons, Inc.

The author is chief chemist of the Park Steel Works of the Crucible Steel Company of America, and his work is devoted to the development of rapid methods, especially for routine work. He covers all phases of the treatment of alloy steels, including annealing and sampling. Numerous methods are given, together with results obtained and precautions required. There are some reprints of papers presented by the author before the American Chemical Society. Methods of analysis of pig iron, carbon steels, together with chapters on raw materials, oils, coal, crucibles, etc., are included.

Plans are given of the Park Works Laboratory, together with photographs, and a description of special appliances, an annealing furnace and a water still. Special apparatus are described and illustrated, and particular attention is given to the laboratory electric furnace. It would have been a valuable addition had the author added an account of his elaborate methods of personal supervision and control over his laboratory force; this should be done in another edition. The book is otherwise most complete and valuable. It should occupy a well deserved position in all steel laboratories.

* * *

**The Metallurgy of the Non-Ferrous Metals.**—By **William Gowland, F.R.S., A.R.S.M.**, 496 pages, 195 illustrations, 4 folding plates. One of a series of treatises written by associates of the Royal School of Mines. Price $5.00. London: Charles Griffin & Co.; Philadelphia: J. B. Lippincott Co.

This book is one of the series edited by the late Sir Roberts-Austen and whose authors are largely his old pupils. As such it deserves respect and attention. This book in particular is not up to the high standard of the series, for it is merely a compilation of data taken from standard American treatises such as Hofmann's, Peters' and Ingalls', and data from the American technical journals. The compilation is, however, well done, and while not as extensive as might be wished, yet the condensed product is available for use by the busy metallurgist, and the book is one which might well be on the shelf of the metallurgical engineer.

## "Chemistry in America"

For a brilliant leadership of many years, for many a great advance in science, for many a word and many an act of wise counsel and hearty encouragement, the chemical profession of America is indebted to Edgar F. Smith, Blanchard professor of chemistry at the University of Pennsylvania and provost of this venerable American institution of learning. But no more delightful gift has ever been made by him to his fellow chemists than his recent book on "Chemistry in America." It is a charming book, this story of the early days of chemistry in Philadelphia—a charming story of strong individualities — Woodhouse, Priestley, Cooper, Silliman, and Robert Hare.

In this book we find the annual oration delivered before the Chemical Society of Philadelphia (the oldest chemical society in the world) on April 11, 1798, by Thomas P. Smith. From this address we quote the concluding sentences: "Living as we do in a new, extensive, and unexplored country, separated by an immense ocean from all other civilized nations, we must feel ourselves deeply interested in a knowledge of its mineral productions and this can only be arrived at through the medium of chemistry. As far as our very limited knowledge has yet gone, we have every reason to believe that nature has been far from bestowing her blessing upon it with a parsimonious hand. Abounding as it does with the richest ores of the most valuable metals, we should be committing a crime of the blackest dye, were we through *wilful ignorance* to trample under our feet these invaluable gifts of the Creator.

"The only true basis on which the *independence* of our country can rest are agriculture and manufactures. To the promotion of these nothing tends in a higher degree than chemistry. It is this science which teaches man how to correct the bad qualities of the land he cultivates by a proper application of the various species of manure, and it is by means of a knowledge of this science that he is enabled to pursue the metals through the various forms they put on in the earth, separate them from substances which render them useless, and at length manufacture them into the various forms for use and ornament in which we see them. If such are the effects of chemistry, how much should the wish for its promotion be excited in the breast of every American. It is to a general diffusion of a knowledge of this science, next to the *virtue* of our countrymen, that we are to look for the firm establishment of our *independence.*"

These sentences are as fresh and as true to-day as they were 116 years ago. They raise the question as to the advance made in this period. What a grand and glorious advance has been made in one way, we appreciate by considering simply the present status of American metallurgy in this country's life and in the world's work, while non-metallurgical chemistry has long outgrown agriculture and is conquering daily new fields and creating economic values. But there is another side to the picture. Does the average American—the average business man and the average professional man—grasp any more clearly now than in 1798 the fundamental importance of chemistry in our industrial life? Does the average American now grasp the idea of Smith that it is to a general diffusion of chemical knowledge that this country is to look for the firm establishment of its independence?

A few weeks ago these questions would have been answered truthfully in the negative. But the European war is doing wonders in driving some fundamental facts home to our greatly astonished fellow-citizens. A clearer understanding by the public of the functions of chemistry and of the chemist must be the result. There are innumerable industrial problems that must be solved and can be solved only by the chemist. For the American chemist the situation is full of opportunities —and responsibilities.

## Progress in Fume Recovery

The tremendous amount of costly experimental work that has been done in the treatment of fume from pyrometallurgical operations is beginning to bear fruit commensurate with the preliminary outlay of time and money. Two phases of the problem have had to be considered: the abatement of nuisance arising from the discharge of noxious gases into the atmosphere, and the recovery of metallic waste. The latter is presented in practically every smelting works, regardless of location, and usually both must be solved. In the case of abating a nuisance, the additional problem is presented of making by-products of sufficient value to offset the cost of their recovery, so that if possible the net cost of operation shall not be increased.

A review of the progress that has been made in smelter-fume treatment indicates that the elimination of sulphur dioxide still awaits the commercially demonstrated successful process. Solid constituents of furnace gases can be settled in flues, collected in bags or precipitated electrically by the Cottrell process. Sulphuric acid can be neutralized with metallic oxides, usually zinc, and gathered in bags, or it can be collected also by electrical precipitation together with dust. But none of these methods affects the sulphur dioxide, which escapes to the atmosphere and causes more or less damage depending on the amount of natural or cultivated vegetation near the smelter.

A method of promise for the elimination of sulphur dioxide, and the recovery of elemental sulphur from ores and mattes, is that of Hall, described elsewhere in this issue. By this process the sulphur in sulphide ores is converted into a by-product of value. Sulphur dioxide in the stack gases is reduced to a negligible quantity, far below the amount permissible under the present terms of legal injunctions against smelters. Like other pioneer processes, this one has shown sufficient merit to warrant further testing and experiment; but immediate extension of the work is prevented by the war.

Another possibility in the elimination of sulphur dioxide from furnace gases, which we understand is being investigated, is the use of di-calcium phosphate as an absorbent. It seems that some work by a German chemist suggests the possibility of using this chemical in a cyclic process in which sulphur dioxide might be absorbed at a comparatively low temperature, and later driven off at a higher temperature and condensed.

Returning to electrical precipitation, it is worth while to note some recent developments of importance: a change in the form of the precipitating apparatus, and the possibility of fractionally separating and precipitating the constituents of a furnace gas by varying the temperature.

The former type of treater consisted of metal plates with intermediate wires, the plates forming the collecting electrodes and the wires the discharge electrodes. The type adopted in one of the latest installations consists of iron pipes 5 in. in diameter and 10 ft. long forming the collecting electrodes, with discharge wires supported centrally in the pipes. This form of treater is proving satisfactory, and experiments are being made with pipes up to 18 in. or 20 in. in diameter to meet various conditions.

The discovery that fractional precipitation can be made by successively reducing the temperature of the gas, holds new possibilities; and while it is too early to announce results of this development, its importance will be appreciated when the complex composition of furnace gases is considered.

Still another interesting recent development in electrostatic precipitation is the process for detarring gas described in the American Gas Institute paper of Mr. F. W. Steere. As described elsewhere in this issue, the chief difference from the Cottrell process—and apparently a quite important one—is the use of alternating current instead of high-tension direct current.

## Opportunity for Metallurgical Development Due to the War

While the domestic non-ferrous metal market continues generally dull on account of the war in Europe, there is evidence that in some instances an opportunity exists for new development in this country and a readjustment of the world's metal and mineral industry. We may cite three instances: tin, arsenic, and magnesite. European sources of these materials have played a large part in supplying our own demands, as a brief analysis of the statistics will show.

Among the world's nations the United States is reputed to be the largest consumer of tin. As a producer she is a negligible factor. The value of our tin imports in 1913 was over $47,000,000; the quantity was about 40 per cent of the world's production. Our own output during the same period was 84 tons of 60 per cent concentrates, valued at about $37,000. As we have no important tin deposits, our opportunity lies in the establishment of a tin-smelting industry to treat concentrates that have been going to Europe for reduction. A supply is reasonably close at hand in Bolivia. That country sends annually to Europe concentrates containing 20,000 tons of metallic tin, which is only a fraction of our annual imports. With a dependable supply of ore and competent American metallurgists to design and operate reduction works, the remaining obstacle is a merchant marine to transport the ore.

The consumption of white arsenic in this country last year was roundly 7200 tons, of which we produced only about 2500 tons. The remainder was imported largely from European countries. Arsenic has been a troublesome element in the smelting industry, and while a considerable quantity has been recovered the output could be increased if there was a greater demand and prospect of better prices.

Domestic consumers of magnesite have been dependent mainly on foreign sources of supply. We imported last year 172,591 short tons and produced only 9632 tons. Since Austria-Hungary has supplied the major portion of our imports, the improbability of placing reliance on that source is apparent. Local supplies may be had in California, and although at some distance from Eastern markets, it may be possible to deliver this material cheaply on the Eastern seaboard via the Panama Canal. The Californian deposits are reported to be extensive and high-grade, and the time seems opportune for the advancement of this industry.

### The Steel Corporation Dissolution Suit

The case of the United States against the United States Steel Corporation is now before the judges, just three years after the suit was brought. In the past month the voluminous briefs have been filed and the oral arguments made, before the Circuit Court of Appeals at Philadelphia. There is left, however, an appeal to the United States Supreme Court, in case either party can find grounds for objecting to the decision now awaited, or in case the judges disagree.

While the briefs and arguments on either side deal principally with facts, or alleged facts, the case, of course, really hinges upon the law, and not indeed upon the strict letter of the law, as to how it should be interpreted, but upon how it should be applied. We are now more or less accustomed to seeing the courts decide "trust" cases and order various forms of dissolution, and it is well to point out that all such practices have been built up by the courts. The Sherman law says nothing about dissolutions. It prescribes for any person found guilty a fine not exceeding $5,000, or imprisonment not exceeding one year, or both, and then prescribes that the term "persons" shall include corporations. In case a corporation formed by the purchase of separate units is determined illegal, the Sherman law gives the court no light or guidance other than the bare declaration that the thing is "illegal." It says nothing whatever about dissolutions, that procedure, as in the case of the Standard Oil and Tobacco companies, having been devised solely by the courts under the common law principle that where there is a wrong there must be a remedy, hence the courts have been forced to devise a remedy.

The case of the Steel Corporation becomes peculiarly difficult, because the evidence, about the substantial truth of which there is practically no controversy, shows that the conduct has been progressively better and better. Indeed, the brief of the corporation counsel in substance admits that the consolidations prior to the formation of the Steel Corporation on April 1, 1901, such as the wire, tin plate and pipe mergers, were formed absolutely for the purpose of reducing competition, asserting indeed that such competition was proving ruinous and destructive. As to the conduct of the Steel Corporation itself, the government contentions are chiefly as to what occurred in the early rather than in the later years. Inasmuch as the law prescribes no punishment other than a fine not exceeding $5,000, and imprisonment not exceeding one year, it does not seem that the corporation could be ordered dissolved as a means of punishment for what is passed, even if such punishment could be made to fall upon those guilty. If the court proceeds upon the basis of righting an existing wrong, then it is important to note that the wrongs shown in the testimony and referred to in the arguments, grew progressively less and less.

It is important to note that much has occurred in the steel trade during the three years since the suit was filed, and much that is favorable to the Steel Corporation. Many instances of good conduct were claimed by the Corporation, and admitted more or less by the government, and referring chiefly to the years immediately preceding the filing of the suit. In the three years since then a great deal more of the same character has been developed. There has been a still more open and competitive market. The average of prices has on the whole been lower. The condition of workmen has been improved still more. Indeed, of all the safety and welfare work done to date by far the major part has been done in the past three years. Exports reached a much higher level in 1912 and 1913 than in any previous year. It might be rejoined that possibly the United States Steel Corporation has been particularly "good" during the three years' progress of the suit, but that contention could hardly carry any weight in a court that had assumed the burden of finding a remedy for a discovered wrong; the court would naturally take the condition of the present. We assume that in an appeal to the Supreme Court, at any rate, means could be found for bringing the evidence up to date.

It is interesting to reflect how little interest is popularly manifested in the once famous steel suit. For several months prior to the bringing of the suit it was currently said in the steel trade that business was halting because the suit was impending, and it was predicted that if the suit were brought the steel trade could not become prosperous until it was settled, but the history is that less than a twelvemonth after the suit was brought the steel industry was operating at full capacity and prices were considerably advanced. The whole gamut up and down has been run once, and the steel suit is perhaps still far from its final adjudication.

# Readers' Views and Comments

## Firebrick

*To the Editor of Metallurgical & Chemical Engineering:*

SIR:—I am interested in an article in your August issue by Mr. J. E. Johnson, Jr., which relates to the firebrick business.

From his article I am led to believe that Mr. J. E. Johnson, Jr., is under the impression that the only purpose for which a firebrick is used is in a blast furnace, when he criticises firebrick manufacturers maintaining the standard size of a firebrick at 9 by 4½ by 2½. As a blast furnace is only one of many thousand places where firebrick are used, the manufacturer cannot follow the whim of the blast-furnace superintendent in maintaining his standards at the expense of all the other different users.

A brick smaller than the standard 9-in. square brick costs more to make, owing to loss in warpage and breakage in both the drying and the burning.

The standard sizes of firebrick as adopted by the Refractories Manufacturers' Association comprise all of the *usual* shapes and take a base price, this base price being determined by each manufacturer for himself. It costs more to make the *unusual* thing than it costs to make the *usual* thing. Therefore, based on cost, the firebrick manufacturer is entitled to more money, based on the 9-in. equivalent, when making those sizes which are larger than 9-in. standard.

Mr. Johnson states in his article that it is his opinion, the reason why the manufacturer charges about 20 per cent more for these *unusual* shapes than for the *usual* shapes, is "apparently that he needs it." I would ask if that is the reason why, when purchasing steel, a consumer pays a certain base price for one size and an extra over this base for another size. In this matter of "extras," I was very much interested in an address of a very prominent steel manufacturer given before the Iron and Steel Institute at their meeting last spring in Chicago, and I would suggest that Mr. Johnson refer to this address. It would be interesting to many of your readers to know Mr. Johnson's reasons of the necessity of these "extras" in the steel business.

CHARLES S. REED.

Chicago Retort & Fire Brick Co.,
Ottawa, Ill.

* * *

*To the Editor of Metallurgical & Chemical Engineering:*

SIR:—I am greatly obliged to Mr. Charles S. Reed for his communication on my treatment of the question of firebrick for furnace lining in your August issue, particularly for his comparison of the "extras" on firebrick with those on steel bars, as this comparison furnishes an excellent illustration of my point.

The shapes of which I spoke are the standard ones, Nos. 1 and 2 in keys 9 in. and No. 2 and 4 keys in 13½ in., and the "squares" or straights of those sizes, all of standard thickness, either 2¼ in. or 3 in. These are illustrated as the standard shapes in all the catalogs of firebrick that I have seen. But as I never have seen a catalog of the Reed blast-furnace brick, of course, I don't know whether these are standard with his company or not.

These may be compared with 1-in. and 1½-in. rounds and squares in steel bars.

Now if the price of the latter be made on 1-in. bars as a base knowing that it takes more labor or limits the output to roll a ¾-in. rod, we would naturally expect to pay more per ton for it, though we might be surprised if we had to pay the same price per foot.

This is analogous to the keys of the 9-in. brick; we can see that it costs more per ton to produce them than it does to produce 9-in. straights and the increased price per ton due to their taking the same price per piece is natural and does not arouse any protest that I have ever heard of.

Now let us turn to the case of 1½-in. bars; this is obviously similar to that of the 13½-in. brick. They require less labor and less overhead to produce than 1-in. bars. Do the steel makers say: "We are sorry but we are compelled to charge $2.50 per ton 'extra' for these bars because they are hard to handle"—or could they carry out such a sales policy if they tried? Ask one and see what he says. Yet that is exactly similar to the policy of the brick manufacturers at which my comment was directed.

I believe that Mr. Reed's comparison thus expanded will make clear to him the anomaly in firebrick prices to which I alluded in my article and if Mr. Reed can now explain this anomaly in terms comprehensible to the blast-furnace man with his admitted ignorance of firebrick manufacture in most cases, he will confer a favor on me and, I believe, on many other furnace men.

J. E. JOHNSON, JR.

New York City.

---

## Grinding Ore for Cyanidation: A Suggested Modification for All-Sliming Practice

*To the Editor of Metallurgical & Chemical Engineering:*

SIR:—The general points made by Mr. Pentland, in his article in your October issue, are very well taken as to the necessity of a thorough investigation of the method to be used for treatment of a given ore, in order to provide the most efficient treatment for all portions of it.

I think it has been too common, in testing and in actual operation, to fail to recognize that reground sand is a different ore from the original slime formed from first grinding, although a screen test may eventually be the same on the two materials. I do not question what Mr. Pentland says regarding the necessity of longer agitation, and perhaps the use of a stronger solution, to make the economic recovery from the reground sand; although on the gold ores of the Black Hills, to which he refers in one place, we found that there was nothing gained by using either stronger solution or longer period of agitation on the fine sand, above that required for the slime.

The best method of giving the reground sandy material a separate treatment, providing that tests showed it to be profitable on the whole, is open to question. I would say that Mr. Pentland's proposal to agitate the partly ground material might require a greater total of agitating capacity than the method of agitating all the reground pulp together with the slime, after the first thickener. Where, however, one classifier is used for separating the tube-mill feed from the original slime, and other classifiers are used for removing the reground sand from the tube-mill discharge, his methods would be entirely feasible, except that unless the agitation were done at the dilution of the overflow of these secondary classifiers, it would seem that an additional thickener should be interposed between the classifier and the sand agitators.

In continuous agitation it is usually considered necessary to have at least three agitators in series in order to avoid short-circuiting. Consequently, with separate agitation of the sand and slime pulps, this would mean that the total number of agitators in use would have to be doubled, except in very large plants where the time of agitation is so long that, in order to avoid too large units, more agitators are used than are necessary to avoid short-circuiting. It is well recognized, I think, that with all classes of agitators, and especially with the one I have developed, the cost per cubic foot of agitating capacity decreases with the increase in size of the unit used, so that the cost of three large agitators would be very much less than for six smaller ones. The operating cost for a large unit will also be less per cubic foot of capacity.

I cannot see where agitating the two products separately would affect concentration, as it would undoubtedly be the tube-mill discharge which would be concentrated. Mr. Pentland's suggestion of sending the slime formed from the concentrating tables directly to the thickener, while the sand that needed regrinding would be returned to the classifier, is perfectly proper, but I do not see that it has anything to do with the points made regarding agitation.

Mr. Pentland has discussed the question of our practice of precipitating only the solution from the first thickener, and not the solution from the thickeners following the agitators. Apparently he regards the circulation of this gold-bearing solution through the stamps or grinding apparatus, as likely to cause loss from leakage, etc. The point is well taken; but he has overlooked the fact that if you precipitate from the overflow of the thickener following the agitators, as well as the overflow of the first thickener, it will be necessary to precipitate a great deal more solution per ton of ore in order to have the same final loss, where continuous counter-current decantation is practiced. The cost of this additional precipitation is a very definite one which can be figured quite accurately in advance, and which I believe will greatly exceed the chances for loss in a well-constructed mill, by circulating a somewhat higher-grade solution. In my mind the limit of the value of the solution to be circulated depends upon the efficiency of precipitation, for very low-grade barren solution is essential in continuous decantation.

The Dorr agitator is well adapted for selective agitation, that is, for agitating the coarser or quicker-settling particles of ore a longer period than the finer particles in the same agitator in continuous work; but this would not necessarily allow the finer particles of sand to have a longer or different treatment from the equally slow-settling particles of slime. Mr. Pentland points out that the method he suggests may allow less mechanical loss of cyanide; but if he will note that in a normal flow in continuous counter-current decantation the battery solution coming from the first thickener goes directly to the zinc boxes and from there to the thickener next to the last, he will see that this is the solution the strength of which should be kept as low as possible.

To sum up I would say that if other considerations made it seem advisable to operate tube-mills and classifiers in closed circuit, it is not likely to pay to agitate the tube-mill return, containing partly ground material, separately from the final classifier overflow. If, on the other hand, a separate classifier is used for the reground material, and it can be operated at a dilution of, say, 3 to 1, which dilution is a satisfactory one for agitation, then the agitation of the reground sand might prove quite profitable. The point certainly deserves careful consideration in designing a mill, and Mr. Pentland is to be thanked for calling the attention of metallurgists to it.

J. V. N. Dorr.

New York City.

## Is There a Complex-Ore Problem?

*To the Editor of Metallurgical & Chemical Engineering:*

Sir:—I agree with Mr. Skinner that in the United States so far the flotation process has only been a success on one-mineral separation, the reason being either that metallurgical knowledge is not sufficiently advanced to apply it to complex ores or that there are no payable ores that cannot be treated by ordinary mechanical means. But perhaps only capital is lacking.

I do not agree with Mr. Skinner that "everyone engaged in the metallurgical field is well aware of the work done in Australia." If he is correct, why has the United States been so backward in making use of the process?

Regarding my statement that "it might be worth while to have some experiments made with Colorado complex ores," he says "I already have the proof and he admits that he has not." What proof? Incidentally, I have admitted nothing. He then admits that he has recommended the flotation process "as a subsidiary to the other general operations" (in dealing with Colorado ores). How does he reconcile this with his previous statement that he does not know of any complex ore in Colorado that could possibly show any advantage under this (flotation) treatment?

He then goes on to say "our ores, as a rule, are rather coarsely crystalline so that it is not a difficult matter to make a proper separation by ordinary mechanical means." In other words, he admits that these so-called complex ores are not complex at all. I thought he was referring to ore that so far could not be treated at a profit, and my contention was that the flotation process might be applied profitably to that class of ore.

As Mr. Skinner is so fully cognizant of the work being done in Australia, he must surely know that "selective flotation" is only used on ore, slime or concentrate that is not amenable to ordinary concentration. In that case it would return a much greater, instead of (as he says) less profit to the mine than the "ordinary older means of mechanical separation." It certainly requires operating efficiency (as he says), but is not so expensive as he imagines.

Mr. Skinner's last paragraph is so vague that I am at a loss how to reply to it. If he will specify what proofs he requires against which statements of his, I shall endeavor to supply them. With which situation do I not even admit familiarity? After that there may be further argument. W. Motherwell.

Nacozari, Sonora, Mexico.

* * *

*To the Editor of Metallurgical & Chemical Engineering:*

Sir:—Your September number containing Mr. W. Motherwell's comments on my contribution to "Is There a Complex Ore Problem?" has come to my attention.

His reference is to a quotation of mine about an ore containing 5 oz. of silver per ton, 14.5 per cent lead, 13 per cent zinc, and 0.25 per cent copper, and his assumption, from a similarity of composition, is that this ore was mined at Broken Hill, Australia; as a matter of fact, the ore came from Utah and contained, in addition to the above metals, a large percentage of pyrite which rendered it wholly unadapted to ordinary mechanical concentration. (The insoluble assayed 12 per cent to 13 per cent.) It is possible that this ore might give a fair separation with some flotation method, and I have heard that one already tried has been partly successful. If Mr. Motherwell or any other metallurgist has any solution for this problem, I should be very happy to forward his scheme of treatment or to put him in direct communication with the owner of this property.

In regard to his second comment, stating that the total extraction at the Broken Hill South mine during

| | | Metal Contents | | | | | | Per Cent of Total | | |
|---|---|---|---|---|---|---|---|---|---|---|
| | Tons | Pb % | Ag oz | Zn % | Pb Tons | Ag oz | Zn Tons | Pb | Ag | Zn |
| Feed | 168,957 | 14.7 | 7.3 | 14.5 | 24,836 | 1,233,381 | 24,493 | 100 | 100 | 100 |
| Lead cones | 27,594 | 68.1 | 24.4 | 6.6 | 18,782 | 673,465 | 1,821 | 75.8 | 54.2 | 7.4 |
| Zinc tailing | 107,279 | 3.5 | 3.6 | 17.6 | 3,754 | 386,204 | 18,881 | 15.1 | 31.3 | 77.1 |
| Quartz tailing | 12,409 | 1.3 | 1.4 | 5.3 | 161 | 17,372 | 657 | 0.6 | 1.4 | 2.7 |
| Slime | 21,675 | 9.6 | 7.5 | 14.8 | 2,080 | 162,562 | 3,208 | 8.4 | 13.2 | 13.1 |

the second half of 1913, as quoted in the *Mining and Scientific Press,* was 91 per cent lead, 85.6 per cent silver and 84.2 per cent zinc: I have been at pains to find how this extraction was calculated. A fuller account and analysis of the half-yearly report is given in the *Australian Mining Standard* for March 15, 1914, page 186. From this it appears that four products are made: lead concentrate, zinc tailing (for delivery to the Amalgamated Zinc Company), quartz tailing (used as a filling underground), and a slime (stacked for future treatment).

The accompanying table shows the products obtained, the weight of metal produced in each case, and the percentage of total belonging to each class of concentrate. In the *Mining and Scientific Press* the extraction given was obtained by adding the percentages saved in the first two classes, and I believe you will agree with me when I state that this does not give a true result for the total extraction. In the lead concentrate there is 6.6 per cent zinc, amounting to 7.4 per cent of the total zinc in the ore, and while this is saved along with the lead, no credit is given for it in the commercial results; along with the zinc tailing is 3.5 per cent lead amounting to 15.1 per cent of the total lead in the ore, and for this it is exceedingly improbable that any credit would be given.

With regard to the extraction of zinc from this tailing, no figures are given but the credits received in selling the ore amount to from 85 cents to $1.25 per ton, while the gross value of the ore sold to the Amalgamated Zinc Company, with lead at 4 cents per pound, silver at 50 cents per ounce, and zinc at 5 cents per pound would be $22.20. These figures would indicate a commercial saving, which all will admit is the basis of successful mining, of approximately 5 per cent. The assumption that 100 per cent extraction is made from this product, therefore, is very far from being accurate, and Mr. Motherwell's citation is unfortunate and in error.

With regard to the slime product from a lead or copper ore being refractory, I am aware that there are several methods of making a low-grade concentrate from it. If Mr. Motherwell has any way of making a high-grade concentrate from such a product, it would be of great interest to have it more fully explained, rather than hinted at, and I feel sure that there would be a good market for this process.

S. A. Ionides.

Denver, Colo.

## True Chemical Energies of Combination

*To the Editor of Metallurgical & Chemical Engineering:*

Sir:—In your August issue Dr. Carl Hering writes of his investigation of whether it is a mere coincidence or likely to be a possible law that the true chemical energy of each bond between like elements is the same.

It occurred to me that the figures could be made to support this more closely if account was taken of the different kinds of bonds between like elements. In Dr. Hering's table (page 527) the first compound is $CH_4$—here all the bonds are alike, a single bond between carbon and hydrogen—therefore the energy between carbon and hydrogen equals the chemical energy of the compound (+ 61.0) divided by 4 = 15.25. But the next compound $C_2H_2$ has two kinds of bonds. It may be written $H - C \equiv C - H$. The value of the two single bonds equals + 30.5, subtracting this from the chemical energy of the compound (+ 32.8) leaves + 2.3 as the value of the triple bond between two carbon atoms. The third compound is written $H_2 = C = C = H_2$. By the same method the value of the double bond is found to be + 8.6 and of the single bond between two carbon atoms + 16.0.

Energy between hydrogen and carbon atom = 15.25 kilogram calories.

Energy between 2 carbon atoms—single bond = 16.00 kilogram calories.

Energy between 2 carbon atoms—double bond = 8.60 kilogram calories.

Energy between 2 carbon atoms—triple bond = 2.30 kilogram calories.

With these four values the chemical energies are calculated by writing out the structural formula, giving each kind of bond its value and adding together. The results are tabulated below and are arranged with each series of compounds grouped together.

| Compound | Chemical Energy | Calculated Energy | Difference |
|---|---|---|---|
| $C_nH_{2n+2}$ | | | |
| $C_3H_8$ | + 156.8 | + 154.0 | — 2.8 |
| $C_4H_{10}$ | + 203.5 | + 200.5 | — 3.0 |
| $C_nH_{2n}$ | | | |
| $C_3H_6$ | + 116.9 | + 116.1 | — 0.8 |
| $C_4H_8$ | + 171.0 | + 162.6 | — 8.4 |
| $C_5H_{10}$ | + 217.8 | + 209.1 | — 8.7 |
| Benzene | | | |
| $C_6H_6$ | + 241.3 | + 165.3 | — 76.0 |
| $C_7H_8$ | + 289.3 | + 211.8 | — 77.5 |
| $C_8H_{10}$ | + 330.0 | + 258.3 | — 71.7 |

This table contains those compounds of which there are more than one of a series in Dr. Hering's table. Except for the compound $C_3H_6$ there is a constant difference between the two values for each series of compounds. Does this mean that the energy of condensation is a constant for each series of compounds?

Oscar Brophy.

Philadelphia, Pa.

## Cyanide Practice in the Porcupine District.—A Correction

*To the Editor of Metallurgical & Chemical Engineering:*

Sir:—In the table giving a comparison of methods adopted in the principal cyanide mills at Porcupine, page 636 in your October issue, I note an error in the column devoted to classifiers. The Dorr classifier is used at the Dome mill, and the Colbath at the McIntyre, instead of *vice versa* as published.

H. C. Parmelee.

Denver, Colo.

* * *

*To the Editor of Metallurgical & Chemical Engineering:*

Sir:—In your last issue we note an article in regard to the operation of the Hardinge mills at the McIntyre plant in the Porcupine district. While the remarks ordinarily would be flattering they do the Hardinge mill a great injustice in stating that the material fed to the mill is ¼ in., while in reality it would not all pass a 1½-in. screen. If we assume it to be 1 in., which is not in itself as coarse as is being fed to the mill, still this 1 in. would be sixty-four times the volume of ¼ in. —in other words, the Hardinge mill has received credit for only doing 2 per cent of the actual work it is performing.

This also applies to the Vipond plant, where a similar size material is being fed; in other words, the Hardinge ball mill is taking a stamp-mill feed.

H. W. Hardinge.

Hardinge Conical Mill Co., New York City

## The Non-Ferrous Metal Market

A general decrease in prices has marked the metal markets during the past thirty days. Regular copper quotations have not been resumed, and the prices at which sales are made are erratic and much below normal.

**Copper.**—Domestic demand has not improved much, and exportations are small. Sales have been made at about 11.5 cents, and there seems to be no immediate hopeful outlook for improvement.

**Tin.**—The demand for this metal has fallen off, and prices have consequently declined. The latest quotation is about 29¾ cents, New York.

**Lead.**—New York price has been reduced to 3.5 cents per pound, with little effect in stimulating business. St. Louis quotes 3.35 cents.

**Spelter.**—Both domestic and foreign demand has fallen off and prices are lower. The decline has been steady to about 4.65 cents, New York, and 4.50 cents, St. Louis.

**Other Metals.**—Quicksilver continues strong, with New York prices ranging about $55 per flask of 75 lb. Business in antimony has been fair, with prices from 11 cents to 13 cents for various brands. Quotations for aluminium are 18@19 cents, New York, with little actual trading.

---

## The Iron and Steel Market

The iron and steel market has dropped to the lowest depths of stagnation seen for many years, perhaps, indeed, since the steel trade replaced the iron trade about a quarter century ago. The stagnation is due more to a mental than a physical state. Demand is light, not because buyers are overstocked, because prices are too high or because physical conditions do not call for the consumption of steel.

The depression is due in part to financial conditions and in part to extreme timidity on the part of buyers, bordering upon panic. It is not difficult to trace the development of thought through which the present condition was brought about. Immediately upon the inception of the European war the steel trade was filled with talk of an immediate expansion in demand, both domestic and export, and with fears that there would not be ferromanganese and magnesite sufficient to permit the steel being made that would be called for. A distinct though slight buying movement about the middle of August furnished concrete evidence that these views were more or less accepted in practice. Later it became certain that there would be no scarcity of any raw material and that the export demand would, for a time at least, prove very light. Money became tight immediately after the war started, but evidently it was weeks before business men realized how seriously the condition would restrict industry. Thus, on account of mistakes in judgment made in August the full measure of the depression has developed only of late, when with a quicker apprehension of the true state of affairs it is not impossible that by this time we should have been able to set ourselves on the road to recovery.

Steel buying has been constantly diminishing and has now reached a very low ebb, the total bookings, in specifications against contracts and in new purchases, chiefly the former, probably not comprising more than 30 or 35 per cent of the existing capacity. Declines in production have followed declines in buying, until at the close of October the average rate of steel mill operation is only about 40 per cent of capacity, against an average between 65 and 70 per cent of capacity during July and August.

Never before, as already indicated, has the steel market reached such a stage of stagnation. In all previous instances there has been a rebound when the rate of production dropped to about 50 per cent, but precedents are regarded as no criterion as to what may occur under these war conditions. So many mistakes having been made already, however, that the conservative observer need not take the popular judgment as final. Perhaps, after all, recovery will set in sooner than is generally expected.

The export demand for steel mill products is running at a rate well under the rate obtaining in the first half of the year, even though that rate, some 140,000 tons a month, was far below the record rate, about 245,000 tons as the monthly average of 1912. There is no prospect of any early and important improvement. The buying capacity in our regular export markets has been greatly reduced, and particularly in South America. The new export demand, for England, which early in the war gave considerable promise, has proved to be light, as activity in the British steel trade is so light that the flow of unfinished steel from Germany and Belgium, stopped by the war, does not necessitate the placing of any large orders in the United States. There has been, however, a fairly heavy demand for barb wire and nails from England, and to a lesser extent from Russia.

At midsummer stocks of finished steel in the United States were thought to have reached the lowest possible level, but they are now much smaller. Nothing approaching a close estimate can be made as to the actual rate of ultimate consumption, since the war has practically stopped the inception of new enterprises, while an indeterminate part of the consumption in recent weeks has been in projects already in course.

In one direction there has lately appeared considerable promise of improvement. While the steel trade has not directly felt any stimulus in export demand for its products, a considerable export demand has undoubtedly appeared in several other directions, including some industries that consume steel. Some large orders have been placed, for instance, for motor trucks and for lathers and other machine tools for export.

Steel buying has been so extremely light that prices are not seriously tested, but there has been a more or less declining tendency nevertheless, and where the end will be cannot be guessed. If the cost of production has been the determining factor in previous declines, and is to determine at this juncture, then the decline will not be to as low a level as in the past, for the mills will have a lower rate of production and consequently higher costs.

### Pig Iron

The rate of merchant pig-iron production has dropped to the lowest level in many years, and yet some iron is being piled, so that the trend is still towards a decrease in output. Buying is almost absent, but enough has occurred to develop slight declines at several points, and there is likely to be further yielding. Southern pig iron, while remaining at $10, Birmingham, is lower at many delivered points on account of the reduction in freights. The rate to Cincinnati has been reduced from $3.25 to $2.90; to Chicago from $4.85 to $4.50 and to Pittsburgh from $4.90 to $4.55, though practically no Southern pig iron has gone to the Pittsburgh district for years. Prices are now approximately as follows: No. 2 foundry, f.o.b. Birmingham, $10; delivered Philadelphia, $14.20; f.o.b. furnace, Buffalo, $12.25; f.o.b. furnace, Chicago, $13; at valley furnaces (90 cents higher delivered Pittsburgh); Bessemer, $14; basic, $12.75; No. 2

foundry and malleable, \$12.75 to \$13; gray forge, \$12.50 to \$12.75. Ferromanganese has continued to weaken. The English price, on contract, is \$68, Baltimore, but re-sale material is offered for prompt shipment at \$65 or less, and there is practically no buying.

### Steel

A few sales, and a greater number of offerings, have developed considerably lower prices for billets and sheet bars. Consumers have old tonnages still due them and being confronted with very light operations for the near future are buying practically nothing. Billets are quotable at \$19.50 and sheet bars at \$20, at maker's mill, Youngstown, prices at maker's mill, Pittsburgh, being 50 cents higher. Rods are \$26, Pittsburgh, but are practically nominal at that figure.

### Finished Steel

Current prices as far as developed are practically as follows, f.o.b. Pittsburgh, unless otherwise stated:

Rails, standard sections, 1.25c.; for Bessemer, 1.34c. for open hearth, at maker's mill, except Colorado.

Plates, tank quality, 1.10c. to 1.15c.

Shapes, 1.15c.

Steel bars and bands, 1.15c.; hoops, 1.25c., base.

Iron bars, 1.15c., Pittsburgh; 1.00c. to 1.05c., Chicago, 1.17½c., Philadelphia.

Sheets, blue annealed, 10 gage, 1.40c.; black, 28 gage, 1.90c.; galvanized, 28 gage, 2.90c.; painted corrugated, 2.10c.; galvanized corrugated, 2.95c.

Steel pipe, ¾ in. to 3 in., 80½ per cent off list.

Steel boiler tubes, 3½ to 4½ in., 72 per cent off list.

Standard railroad spikes, 1.40c., Pittsburgh; 1.50c., Chicago.

Structural rivets, 1.45c.; boiler rivets, 1.55c.

Cold-rolled shafting, 67 per cent off list.

Chain, ⅜-in. proof coil, 3.00c.

---

## The Western Metallurgical Field

### Heating Mill Buildings

As a general rule the cyanide and concentrating mills of the western United States require heating during the winter season. In some cases it is even customary to heat solutions throughout the year. For both of these purposes steam must be generated, either in conjunction with the power plant, or for the sole purpose of heating when electric power is purchased from a central station. In either event it is likely that live steam is used in most cases, and that heating with exhaust steam is not practiced to a wide extent.

There are neglected possibilities for economy in the use of exhaust steam for heating purposes. If a mill has a steam power plant, and live steam at reduced pressure is used for heating, there is a distinct loss in the waste of exhaust steam from the engines. If, on the other hand, the mill is supplied with electric power from a central station and a steam plant is installed for heating purposes only, the cost of that heating is almost as great as though a corresponding amount of power were first generated and the exhaust steam used for heating.

The relative fuel requirements for heating and for power production are not always fully appreciated. Writing on the subject of Preventable Losses in Factory Power Plants, Mr. David M. Myers gives some illuminating facts in the August number of the *Engineering Magazine*. Among other things he shows that about 90 per cent as much fuel is required to make live steam for heating requirements alone as for the production of power. In one case he demonstrated this by shutting down every engine in the plant and weighed the fuel to the boilers which carried a heating load only, with the result that there was no perceptible difference in fuel consumption. In a case where steam at 125 lb. was lowered to 20 lb. by a reducing valve for the heating system, a 150-hp non-condensing Corliss engine was substituted for the reducing valve, expanding the steam down to atmospheric pressure before it was used for heating. The power thus produced, or about 90 per cent of it, became a pure by-product of the steam heating. It is essential, of course, that an exhaust-steam heating plant be properly designed, for otherwise the beneficial effects cannot be obtained and failure is likely to result.

Another point made by Mr. Myers is contained in the following quotation: "A common error among plant owners is to ascribe undue economy to the heat that may be carried in water resulting from the condensation of steam. They conversely greatly *underestimate* the heat carried in exhaust steam. As a matter of fact the heat in a pound of water at 212 degrees is only 180 British thermal units reckoned above the freezing point; whereas in a pound of steam *at the same temperature* the heat units number 1150. Hence if this steam is condensed in a radiator it gives out 970 heat units, and the drip will contain 180 heat units. Nevertheless I have found the management very anxious about correcting the loss due to a few escaping drips, while at the same time large quantities of uncondensed exhaust steam were blowing away almost unnoticed. Pound for pound, the waste which attracted the manager's attention was equal to less than *one-fifth* of the heat being carried away in the disregarded exhaust steam. This is a good thing to remember, and it will stand twice telling: *Utilization of the exhaust steam saves five times as much coal as the return of an equal weight of hot drips to the boiler.*"

The whole subject of heating with exhaust steam is worthy the attention of metallurgists because it is quite possible that important economies can be effected in connection with the power plant.

### Anyox Smelter of the Granby Company, British Columbia

The new smelter erected by the Granby Consolidated Mining, Smelting & Power Co., Ltd., at Anyox, B. C., was designed to treat the ores from the Hidden Creek mines near Granby Bay, on Observatory inlet, about 110 miles northeast of Prince Rupert.

Each of the three blast furnaces measures 50 in. by 360 in. at the tuyeres. The sole plate is four inches thick and is formed of iron cast about coiled pipe through which cooling water is circulated. There are two rows of jackets; in the lower row on each side of the furnace there are six, each 54 in. wide, and one tap-hole jacket 36 in. wide. All are 10 ft. 6 in. in height. Those in the upper row are 60 in. wide and 6 ft. 8 in. in height. The tuyere openings contain thimbles that are fused to the fire sheet, extending through the air sheet of the jacket and beaded in place. The upper tier of jackets is supported from the mantle frame in such a way that the lower jackets can be removed without disturbing the upper tier.

The mantle frames of the three furnaces are connected, forming one continuous mantle. The sole plates extend beyond the end jackets, and it will be possible to extend the furnaces at any time to occupy the space of 15 ft. which intervenes between the middle and end furnaces, so that a single furnace of 120 ft. in length could be constructed without difficulty.

There are three basic-lined copper converters of the Great Falls type, each 12 ft. in diameter and 17 ft. 7 in. high. Thirteen tuyeres 2 in. in diameter are placed with their axes at right angles to the axis of the shell. The tuyere pipes extend into the converter and are connected with the tuyere casting by a special coupling which permits removal of the casting without interfering with the pipes. Each converter is operated by a 50-hp motor through worm gears.

Additional information on this and other smelting plants in British Columbia is contained in a publication recently issued by the Department of Mines of Canada. The report, which is edited by Dr. Alfred W. G. Wilson, presents a historical review of copper smelting in Canada and includes descriptions of the plants now in operation: Canadian Copper Co., Mond Nickel Co., Consolidated Mining & Smelting Co., Granby Consolidated M. S. & P. Co., British Columbia Copper Co., and Tyee Copper Co.

## New Cyanide Mill for Rochester Mines Co., Nevada

The design of the new 100-ton cyanide mill for the Rochester Mines Co. at Rochester, Nevada, construction of which is now under way, presents some interesting features, particularly with reference to continuous counter-current decantation. The equipment of the sampling department comprises the following machines in sequence: Blake crusher, elevator, No. 3 Vezin sampler, Dodge crusher, No. 2 Vezin sampler, rolls, and No. 1 Vezin sampler. Metallurgical treatment will begin by crushing in solution with ten 1550-lb. stamps. The stamp discharge will be classified into sand and slime in a Dorr classifier specially designed to give extra settling area, being deeper and longer than the standard machines. The grinding will be completed in two 5 ft. by 16 ft. tube mills connected by clutches with a single 100-hp motor equipped with silent-chain drive. The classifier overflow will contain probably 95 per cent of minus 200-mesh pulp.

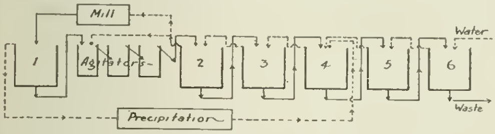

FIG. 1 — SCHEME FOR CONTINUOUS DECANTATION AT ROCHESTER MILL

The equipment for recovery of pregnant cyanide solution will consist of one Dorr thickener 28 ft. by 12 ft., followed successively by three Dorr agitators 28 ft. by 16 ft., and five thickeners 28 ft. by 10 ft. The agitators will be operated in series, with a drop of four inches between successive machines. The last five thickeners have, successively, 2 ft. greater elevation to provide for return of decanted solution by gravity. Diaphragm pumps will be used to elevate the thickened pulp through the series. The pumps will be driven from adjustable eccentrics on an overhead shaft, a 7-ft. rod connecting the diaphragm with the drive. This scheme is expected to materially lessen the wear on the diaphragms due to lateral motion.

The general scheme for continuous decantation which was finally adopted after considering the conditions peculiar to this proposition, is diagrammatically represented in Fig. 1. It will be observed that there are six thickeners, five following the agitators instead of four as is customary in other installations. It was first proposed to use only five altogether, with double precipitation, precipitating not only the overflow from No. 1, but also that from No. 4. Under this scheme, the theoretical calculations indicated a loss of dissolved gold amounting to four cents per ton of ore treated, and a mechanical loss of cyanide equal to 0.61 lb. per ton of ore. The calculations for the present scheme, however, using six thickeners and single precipitation, indicated dissolved loss of about one and one-half cents per ton of ore, and a mechanical loss of cyanide equal to 0.62 lb. per ton of ore.

Comparison of the figures will show that the extra decantation obtained in the sixth thickener, reduced the dissolved loss and still gave about the same mechanical loss of cyanide. A further reason for the adoption of the extra thickener was the possibility of occasionally treating high-grade ore—up to $50 per ton—in which case the extra decantation would be a protection against loss of dissolved metal. It is interesting to note that a 15-hp motor provides power for all operations below the tube mills.

## Chemistry at the American Gas Institute

The meeting of the American Gas Institute, held in New York City from October 21 to 23 in the United Engineering Building, brought out some interesting chemical papers, mostly presented before the new Chemical Section.

A paper of considerable chemical interest, by Captain **Fred H. Wagner** of the Bartlett Hayward Company, of Baltimore, Md., on "coal gas residuals (Feld process)" was presented on October 21 before the Manufacturing Section. It is published in full elsewhere in this issue.

The chief chemical feature of the convention was, however, the inauguration of the newly formed Chemical Section. It was very successful in both its sessions in the morning and afternoon of October 22. While the members were somewhat tardy in coming in, the meeting room filled up very well in time, the attendance being somewhat like fifty. Moreover, there were good spirited discussions and the interest did not flag to the end.

### Gas Analysis

The proceedings of the morning started with a report by **W. H. Fulweiler**, Philadelphia, Pa., for the Gas Chemists' Handbook Committee. The voluminous first report of 118 printed pages gives first an alphabetical index of what should be included in the Handbook, and secondly a description of methods of analysis of ammoniacal liquor, coal and coke, illuminating gas and furnace gas, impurities, gas oil, oxide, and tar. Mr. Fulweiler emphasized that standard methods of sampling were at least as important in practice as standard methods of analysis.

A long discussion followed in which Dr. Morehead and Dr. Elliott emphasized that the ultimate object of the work of the Committee should be a set of standard rules for sampling and analysis which would have to be adopted by the Gas Institute (like the Standardization Rules of the American Institute of Electrical Engineers). These rules would represent the final authoritative say in cases of dispute between seller and buyer of coke, for instance.

A paper on "a method for the determination of hydrogen sulphide in gas" was then presented by **A. B. Way** of Everett, Mass. There was a lively discussion on "pet analytical methods." The general consensus of opinion seemed to be that Mr. Way's method was both accurate and quick.

### An Electrical Process for Detarring Gas

Of considerable interest and great promise for industrial application was the paper by **W. W. Steere**, Detroit, Mich., on a process which he has recently worked out, having formerly been connected with the research work of Prof. A. F. White, of the University of Michigan, on the electrical separation of tar from coal gas by the Cottrell process. While Cottrell uses rectified high-tension direct current, Steere employs alternating current directly. This means simplicity of construction since with the simple use of alternating current the transformer may be mounted on the ionizer, one terminal may be grounded and the other connected directly to the electrode terminal. With the terminals and connections completely enclosed so that no high-tension parts would be exposed, and with no moving parts requiring attention or inspection the element of danger would be absolutely eliminated.

The process was worked out at the Detroit plant of the Semet-Solvay Company. The gist of the process is this: It is practically impossible in mechanical extractors to free the gas from tar in the extremely fine state of subdivision which naturally results from rapid condensation. But there is no difficulty in removing relatively large drops. Now the electrical treatment simply converts the fine mist into large drops.

The gas is subjected to an electrostatic treatment in the "ionizer" operated by alternating current, and the result of this treatment is that the fine mist of minute tar globules is agglomerated into large drops. The gas with the large tar drops is then swept into some form of mechanical extractor where a complete removal is affected with very little power loss. The Doherty centrifugal tar extractor worked very well to accomplish this; the old type P and A machine also became a very efficient tar extractor when placed after the ionizer.

Cleaning producer gas for use in gas engines is one of the later developments of this process and it is noteworthy to state that the process is now in commercial use at the plant of the Ford Motor Company at Detroit on the producer gas driving their large gas engines. The process was started at the Ford plant the 21st of January, 1914, and up to now has not been out of service one minute while the plant was running.

The paper elicited an extended discussion and in reply to the various questions asked, Mr. Steere stated that there is no decrease in calorific power of the gas. No deteriorating effects have been observed on the iron mains in nine months' work. The process is electromechanical rather than electrochemical. At the Ford plant the power consumption is between 1 and 1½ kw. The problem of insulating has been solved completely.

We expect to publish this interesting paper in full in a future issue.

### Calorimeter

A paper on "tests of a new recording calorimeter" was next presented by C. H. STONE, Middletown, N. Y., and W. H. HINMAN, New York City. The instrument, built by the American Meter Company, is a regular Hinman-Junkers calorimeter fitted with a pair of special recording thermometers. The paper was read by Mr. Stone and the discussion closed by Mr. Hinman. In the discussion various speakers emphasized the great commercial need of a reliable recording calorimeter. The instrument was shown in the exhibit of apparatus on the ground floor of the building.

### Bureau of Mines

The afternoon session was devoted to these papers contributed by the Bureau of Mines.

Dr. G. A. BURRELL presented a paper, by himself and I. W. ROBERTSON, on "the separation of the illuminants in mixed coal gas and water gas."

In this paper experiments were described made by the Bureau of Mines and which resulted in separating the illuminants in the mixed artificial gas of Pittsburgh. This gas is made by mixing one part of carbureted water gas with three parts of coal gas. The separation was made fractionally distilling the gas in a vacuum at low temperatures and follows the method detailed by the Bureau in separating natural gases.

Dr. HORACE C. PORTER then presented a paper by himself and GUY B. TAYLOR on "the mode of decomposition of coal by heat." The object of the research was to analyze the process of carbonization in its different steps and to study especially the early steps by making use of a high vacuum with low temperatures of decomposition.

### Gas Manufacture from the Point of View of Physical Chemistry

The last Bureau of Mines paper was presented by Dr. W. F. RITTMAN, who spoke forcefully and very interestingly. The day is past when gas making is primarily a mechanical operation. Carbureted water gas constitutes approximately two-thirds of the gas made today, and it is no longer possible to buy a high-grade paraffin gas oil for 3 cents a gallon. In 1913, Greater New York alone used approximately 3,860,000 barrels of oil in the manufacture of carbureted water gas. During 1913 the same plants used approximately 1,600,000 tons of coal. On the basis of heat units involved, oil has become as important in American gas manufacture as coal. During the last decade, the increasing price of oil for gas manufacture has created what many gas men regard as a "dangerous" situation; and this is true despite the fact that never before in the history of the United States has so much oil been produced as to-day.

The reason for this is to be found in the fact that the oil refiner, by extended research, has perfected processes whereby the oil which the gas manufacturer used to buy at 3 cents a gallon is now converted into gasoline and other products which sell at several times that price.

In a recent court hearing in Chicago interesting testimony was given by Mr. Frank B. Lewis, Jr., manager of the Standard Oil Company refinery at Whiting, Ind., regarding the Burton process. The Whiting plant is running exclusively on Mid-Continent oil. They are able to take it all and convert it all into gasoline except what coke is left in the still, and a little wax or petroleum tailings. The process has been in use for about one year.

Oil refiners all over the country are also working on methods to convert every pound of gas oil into more valuable products. Facing facts, this means that if gas men are to continue the use of petroleum in carbureting water gas, they must resort to one of two alternatives: first, they must greatly increase the yield of gaseous hydrocarbons from a given amount of oil, or second, they must perfect methods of using the millions of barrels of fuel oil which today are considered unfit for carbureting water gas. One often hears the statement that these so-called fuel oils cannot be used in carbureting water gas. What right does any one have to make this statement?

Dr. Rittman thought there is no reason to be pessimistic. He expressed the conviction that as soon as the gas manufacturer faces facts as they are, and seriously attacks the problem, increased efficiency and economy will result with petroleum still of primary importance as a raw material. Never in the history of the world has so much oil been produced as is being produced today. It is estimated that Oklahoma alone will mine 80,000,000 barrels. California will contribute 100,000,000 barrels. Never in the history of the United States has so much oil been in storage as today. We are not facing an oil famine. We are facing a famine of knowledge concerning the chemical behavior of inferior petroleums which will facilitate their substitution for higher-grade petroleums.

Dr. Rittman emphasized the necessity of systematic physico-chemical research at considerable length.

The different papers are copyrighted by the American Gas Institute, subject to the authors' corrections.

## Coal Tar Colors in America*

BY I. F. STONE

It gives me great pleasure to be able to appear before you this evening, to clear up if I can, the general skepticism which seems to exist in connection with the manufacture of coal tar dyes in the United States.

That there is such an industry in the United States is a fact and has been for over thirty years. That we cannot compare with Germany in magnitude is, of course, true, and that we will be able to increase our production in the near future to take over all of the colors now supplied by Germany is also manifestly impossible, but that it is possible to increase the American production very materially is a fact, depending on certain conditions of which I will speak later in my remarks.

That there has been more or less prejudice against dyes made in America is also true, in spite of the fact that these dyes are fully as good as any made in Europe, and it has been a struggle to prove that the latter statement is absolutely true. Even at this late day there are people who would always give the preference to European dyes at the same price and quality, if they had an opportunity to do so, and are abetted in their belief very naturally by the European representatives. Only a few days ago among other letters we have received asking about the manufacture of dyes in this country, was one from a very substantial trade journal which circulates largely among the textile mills. Among other things it says:

"No one believes that the American dyestuff manufacturer can compete with the German. The Germans are counted wizards in dyestuff chemistry, and I doubt if you could interest a great number of manufacturers in a domestic product at the same price as quoted on exactly the same thing from Germany."

After a couple of pages of such argument it finally suggests that we take up the matter of advertising with them to change the sentiment of the buyers, which is very naive to say the least. But the point is if a journal with the influence of this one should express such sentiments among its subscribers, how unfair it would be to the American manufacturers of dyes, and it is simply an instance of one of the small things against which they are struggling.

On the other hand, in the past few weeks we were encouraged by numerous letters from actual consumers of dyes, among them some of the largest textile mills in the country, complimenting us upon the way we have been handling our products during the present abnormal conditions, and advising us that they would in the future give their preference to American colors whenever we are able to offer them in competition with foreign colors; in other words, able to supply them with the quantity of colors consumed, which hitherto we have not been able to do by reason of not having a production sufficiently large to take care of all the trade. So life does have its compensations and the American dyestuff industry from now on, in any event, starts out on an equal footing with the German industry, as far as the good-will of the consumer is concerned, and it is, therefore, only a question of being able to produce a large enough quantity at competitive prices to insure a large proportion of the business of the United States for the American manufacturers.

Barely two months ago a comparatively small percentage of the population of the United States knew anything about aniline dyes or dyestuffs, those who did know something being mainly connected with industries which used these products in their line of business. Even those who did use them had only a vague idea, as a rule, what they were and their source, except in a general way that they were made from coal tar and that Europe was the principal source of supply. They were even regarded by a large percentage of the consumers as a mere detail of their business, and were put in among the sundries with such items as oil, soap, and I might almost say paper, string, and such miscellaneous supplies, notwithstanding that it required the highest order of scientific training to produce these colors and a long experience and knowledge of them in order to sell them successfully. The average dyestuff salesman was received only with tolerance and usually referred to some minor employee of the owner for his interview.

Suddenly something happened. A great war was declared, and the great source of supply was one of the principal nations involved. Some buyer, more intelligent than the ordinary one, discerned that the supply of dyestuffs would be more or less limited if not entirely cut off under these conditions, and immediately made attempts to secure a good supply for his future wants. The news soon spread among others until there was a general scramble for dyestuffs, and men who ordinarily gave this matter very little attention are now looking after it personally, and interviewing and corresponding with the heads of such firms as they thing can supply them with their wants. The newspapers took up the matter and published columns of more or less accurate information as to the situation. The general public was, therefore, given an idea of what was going on, and now know more of the source and supply of aniline products than they ever knew before.

The unfortunate conditions now prevailing have at least been of some good in a small way in educating our people here to the fact that they should be as independent as possible of other nations in connection with their supply of such products as are needed in this country, and there is now a general demand that the production of aniline dyes as one item should immediately be developed to such an extent that we would be independent of all other nations.

The serious question now, therefore, is whether or not such industry can be developed to such an extent, and this question can only be answered by some extended and more or less superficial explanation of conditions. It is not my intention to put before you a scientific or technical paper on the subject, as most of you are more or less familiar with the general conditions surrounding the manufacture of these products, or at least can easily read up in detail in any of the standard publications on the subject. I do wish to give you, however, a practical statement of the facts so that you will see why the industry has not developed in this country as it has in Europe, more particularly in Germany, as other nations are no further advanced than are the United States.

Aniline, as you know, is a product of coal tar, that is, coal tar is the primary raw material from which colors are produced, and it was obtained originally in the manufacture of coal gas, but of recent years a large and constantly increasing quantity has been obtained from the coke ovens used for making hard coke.

The first distillates are such products as benzol, toluol, xylol, phenol (carbolic acid), naphthalene, anthracene, etc., and these are produced largely in the United States as well as in Germany. Benzol, for instance, which is probably the most important of the group, is not only used as a base for the manufacture of intermediate products for the manufacture of aniline dyes, but is also used largely as a solvent in place of benzine and gasoline, and, in fact, in Europe is used largely as a fuel for automobiles as a substitute for the same products. The prices at which it sells in this country are practically the same as in Europe, as are also, in fact, the prices of the other distillates first mentioned.

---

*A paper read before the New York section of the American Chemical Society on October 9, 1914. A report of the meeting will be found elsewhere in this issue. (See p. 684.)

Up to now the supply has kept pace with the demand and there is no overproduction, but if the manufacture of dyes is to be considerably extended it will then be also necessary to extend the production of benzol, and this can be done in the course of time by getting the assistance of those coke ovens which do not at present recover their benzol, to put in appliances for doing so. Their interest in the matter, however, depends on their ability to make a profit on this recovery. There is, therefore, a chance that the price of benzol may increase to some extent for this reason.

Another of importance is naphthalene, which is made largely because there is a large demand for it, the consumption in the United States being upwards of nine or ten million pounds, not alone for its use in the manufacture of dyes but more for its use as a moth preventive, it having a large sale for this purpose all over the land. Of the quantity consumed here about one-third is produced in the United States, while the balance comes about equally from Germany and England.

It is evident, therefore, that the United States starts out on an even basis with Europe as far as the supply of the first raw materials is concerned, and that the natural resources of this country are available for an increase in the products which are manufactured from this source. So, in the beginning, for raw material we are as well placed here as they are in Germany; in other words, this is not a hot-house industry as some people have claimed, but is a part of the natural resources of the United States.

From these distillates are manufactured what we call intermediate products, such as nitro-benzol, aniline oil, aniline salts, toluidine, xylidine, cumidine, benzidine, binitro-benzol, nitro-benzol, sulfo-acids, and a host of other products, a list of which can be had from any good textbook on chemistry if you are interested in looking them up further.

It is here that the first check in the economical manufacture of aniline dyes is encountered, for the reason that with one or two exceptions which I will mention later, none of these intermediate products are manufactured in the United States, because up to now there has not been a large enough demand for them to make their manufacture economically possible, while on the other hand, Europe—Germany particularly– has so developed the demand for these intermediate products that many plants have been established for their manufacture, most of them specializing on certain products, while some specialize on others, so that in the aggregate they are all produced on the most economical basis.

Up to within recent years few of the aniline dye manufacturers manufactured these products themselves, but depended largely on the aforementioned so-called specializing factories for their supplies, but this is now changing and some of the large color manufacturers are now making the principal intermediate products themselves although none of them make everything which they use. It is then very necessary, if the United States is to be independent of Germany, that these intermediate products be manufactured on a large scale in this country, and it is here that we ask the Government to start in with a sufficient protective duty to allow the business to be developed. The present duty of 10 per cent, which was only put on in the last Tariff Bill, is really not sufficient for the purpose, while before that time the group being free of duty there was no incentive to begin their manufacture here.

One exception which is manufactured here is aniline oil, the manufacture of which was commenced about three years ago, and the quantity now produced is about one-quarter, and perhaps more, of the total consumption of the United States, taking oil and salts as one product. The quality is very satisfactory as compared with the German and English products, and has been used by our factory in the manufacture of aniline dyes since the beginning. In fact, if it were not being produced in this country at the present time the American dye manufacturers would not be able to continue to run, as they would be unable to obtain supplies from Europe. Consequently, as a result of this, manufacturers here are able to relieve the scarcity of aniline dyes, and have been of great benefit to American consumers by so doing, and will be a great factor in this relief as long as these unfortunate war conditions continue, so illustrating the great benefit to the people at large in having this class of products manufactured here, and so be entirely independent of Europe, under any conditions.

Unfortunately, however, the commercial side of the manufacture of aniline oil has not been so satisfactory for the reason that in the beginning they had no protection in the way of duty and were compelled to compete on an even basis with Europe, which could not be done successfully. They did, however, succeed in securing a duty of 10 per cent under the present tariff, which went into effect in October, 1913, just a year ago, but unfortunately this did not avail them anything in the beginning for the reason that the convention which controls the production of aniline oil in Europe immediately reduced their prices 10 per cent, to effect this duty so that we were no better off here than before. This is a sample of what is called unfair competition on the part of European firms in their attempt to prevent the increase of the aniline industry in this country, but could be readily checked if our Government would incorporate in their tariff what is known as the "dumping" clause, which is a clause forbidding the importation into and the selling in the United States of any products at a less price than they are sold in the country of production.

In spite of this check, however, the American manufacturers will continue the manufacture of oil, hoping that conditions will change in the near future so that they may be able to do so at a profit, and when this object is attained their plans are then to take up the manufacture of other intermediate products until everything necessary is finally manufactured here. As a matter of further interest, I might say that our own factory in Buffalo made aniline oil thirty years ago, but were obliged to give up its manufacture at that time owing to their inability to secure benzol. This situation is, however, now changed, as sufficient benzol should be obtained to continue the manufacture under advantageous conditions.

The other exception to my statement that these intermediate products are not manufactured here is nitro-benzol, known also as crude oil myrbane, which is in some demand from outside industries as well as the aniline industry, but not to so large an extent as aniline oil, and which is made here from time to time as conditions warrant; in other words, when it can be made at a profit in competition with Europe.

There is another demand springing up for these intermediate products, which may increase their consumption to such an extent that there will be a large demand entirely outside of the aniline industry, for instance, in the manufacture of smokeless powder and other explosives. The manufacturers of these are now using such products as diphenylamine, tri-nitrotoluole, nitro-benzol, pyridine, nitro-naphthalene, etc., and will finally create a demand which will necessitate their manufacture in this country as a matter of safety. For if the Government depended on explosives made from these materials it will in self-defence have to create some sort of subsidy or tariff protection, making it possible for their manufacture irrespective of European competition.

This is also true, by the way, of carbolic acid, which is a primary coal-tar product, and which is used in the manufacture of picric acid, an explosive product used by the Government. Carbolic acid is not being manufactured here at present to any extent and is now being practically unobtainable from Germany or England by reason of these countries having placed an embargo on this product.

From these so-called intermediate products we then come to the manufacture of the actual aniline dyes as sold in commerce, and their number is voluminous and complex. My good friend Dr. Hesse, for instance, recently stated in a published letter that there were some nine hundred different manufactured products, most of them as different each from the other as a pair of shoes is from a pair of socks. Of these nine hundred he observed that some seventy-six are now made in this country, but that this number is apparently not sufficient to meet the users' demand. In this statement I am quite ready to agree with him, except that we now make nearly one hundred types, which is more than he gives us credit for making. I will say, however, that of these nine hundred original types a great many are obsolete and probably we could get along quite well with a much less number, but as the one hundred made in America are all live types and those which can be manufactured regularly, you will see we are making really a much larger percentage of the total than is apparent at first glance.

In fact, I might almost venture the statement that with the hundred or so types already manufactured here, together with perhaps a few more which we would be prepared to take up on short notice, we would be able to furnish the American consumer perhaps 90 per cent of their color demand, speaking now of types or shades and not of quantity. The other 10 per cent which we could not furnish are such products as alizarines, indigo and patented specialties which would require large installations which would take a long time to complete.

It would perhaps be interesting in connection with these colors to give a hasty sketch of their beginning and development until the present time when they have resulted in the great chemical industry of Germany, the investment of millions of dollars and the employment of thousands of people.

The first color discovered was mauve, which is a sort of violet, by Perkin, in 1856. Then followed magenta and fuchsine in the same year, and a small establishment for the manufacture of same in England, which was not, however, very successful. Then came in 1862 the discovery of soluble or water blues, then the discovery of Hofmann's violet about 1863, Bismarck brown in 1863, then naphthol or martius yellow in 1864, nigrosines in 1867.

It was about this period that the Germans became actively interested in these products, and commenced their patient, intelligent and careful researches into the subject, which later resulted in the most wonderful discoveries and the development of this industry in their country.

Then followed the discovery of orange, fast red, chrysoidine, malachite green, ponceau (scarlet), methylene blue, eosines, and metanil yellow about the years 1875, 1876, 1877 and 1878, and the manufacture then became one of recognized merit and importance.

After 1880 followed in rapid succession the discoveries of auramine in 1883, tartarzine in 1884, benzo purpurine in 1884, congo red in 1885, benzo azurine in 1885, naphthol black in 1885, diamine red in 1886, rhodamine in 1887, to mention only a few of the best known and most successful colors.

From 1880 to 1890 might be called the golden period of the business. Just prior to that time alizarine had been discovered, red in 1871, blue in 1877, patented, and successfully produced and sold at high prices with correspondingly large profits, and it was about that time that our German friends discovered the advantage of securing an exclusive market in the United States through their patents, which enable them to sell at high prices here although continuing the manufacture in Germany. The profits from such patented products as alizarine, benzo purpurine, diamine red and other direct dyeing cotton colors, auramine, rhodamine, tartrazine, and other such colors which were discovered and put on the market in that period, were enormous and put the German industry immediately on such a high pinnacle of success that it has continued until the present time.

In the nineties came the discovery of such important products as direct blacks for cotton and acid and chrome blacks for wool, the total consumption of these blacks being much larger than all the other colors combined.

It was also at this same period that began the first of the patents on synthetic indigo, of which there are many, and which was finally put on the market at such a tremendous expenditure that it has only been a commercial success in the past few years, finally being such a success that it has replaced the natural indigo practically altogether.

I might say in connection with the development of colors, that in the nineties came also the development of such pharmaceutical products as phenacetine, antipyrin, etc., which paid enormous profits to the manufacturers and which were also controlled by patents.

Such, then, is the wonderful development of the coal tar industry, there being invested at this time in Germany something like four hundred millions of dollars (probably more) and the employment of some fifty thousand people in factories, paying dividends to their stockholders, some of them 25 to 30 per cent, and that after charging off a third of their profits to sinking funds for the erection of new plants and for other such purposes. In fact, this has been done for so long a period that most of the present property and plants do not appear on their books at all as an asset, but have been built from the surplus profits. This statement is made on the basis of balance sheets for 1913 issued by one of the great factories, this factory having a capital of 55 million marks ($13,750,000), but whose stock is selling for over six times par value, showing that the actual capital in the business was at least four times the shares issued, or some 200 million marks ($50,000,000). On a capitalization of 55 million marks they showed a profit of 25 million, or nearly 50 per cent, one-third of which was written off for their real estate and plant account, leaving about 16 million marks from which they paid a dividend of 28 per cent.

Assuming that I am correct in my estimate of some

400 million dollars being invested in the industry in Germany, and assuming that a fair proportion of their production is shipped to the United States, it would mean that if the United States were to develop this industry to take care of all their consumption here they would need millions of dollars and would need to employ thousands of people. This will give you an idea of the magnitude of the business that it is now proposed that we establish here to its full extent.

It might be interesting at this point to give you the amount of aniline products imported into the United States from these European factories, the figures being for 1913: Aniline dyes, about $7,000,000; Indigo, about $1,000,0000; alizarines, about $1,500,000, a total of about $9,500,000. These figures are, however, cost prices, and when the American duty of 30 per cent is added on aniline dyes, and further amounts are added for expenses and profits on their sale here it means that the American consumers are really paying something like $12,000,000 for their supplies, not counting the colors produced in America, which may perhaps reach about $2,000,000 more, the production in America, by the way, being some 15 to 20 per cent of the total consumption. These figures do not include the importation of pharmaceutical products which are made from coal tar, this being in itself a large business.

Our German friends are entitled to all the benefits which have accrued to them by reason of their shrewd, intelligent and careful attention to this industry, but with such a statement as the above, does it not seem as if they had had enough and it is now time for the United States to participate in this great industry when they are so well prepared to do so by having as good, if not better, natural sources than has Germany, and being consumers of so large a proportion of the German products? We must admit at once, however, that the United States cannot compete with the German manufacturers under normal conditions, first because they have a great advantage in capital, experience, and the general advantage of everything that goes with a successful and enormous business; and second, because the actual expenses of producing in Germany through labor conditions and so forth are much less than in this country, so that some way must be devised that the United States can be put on a competing basis. This can only be done in two ways:

First, by a sufficient protective tariff, which does not necessarily mean, by the way, that this will increase prices to consumers, although many people seem to be of this opinion. For instance, in an article in the *Scientific American* of September 26 they fall into this common error in stating that with an average importation of about $6,000,000 worth of coal-tar dyes in the last thirty years we have a total importation of $180,000,000 during that period, and assuming that duties had been 10 per cent higher than was actually the case this means that a total of $18,000,000 would have been paid as an insurance premium against the possible event of the war such as that which is now distressing commerce. In other words, they mean that the American consumers would have had to pay this large amount of money more if there had been a 10 per cent higher tariff than they had been paying under the various tariffs which had been in effect during that time.

Even if the *Scientific American* were correct in their statement that $18,000,000 would have been paid as an insurance premium in thirty years, this would really be cheap insurance compared to the enormous value of the goods manufactured in which the colors were used, assuming the colors with which to manufacture these goods could not be obtained in the necessary quantities either from Europe or by an increase in the American manufacture. When I speak of goods in which aniline dyes are used I mean a whole range such as textiles, leather, paper, silk, paints and the hundred and one other manufactured products in which the use of aniline dyes is necessary.

In my opinion, however, based on experience, just the contrary to the *Scientific American* opinion is true, for the reason that a higher tariff would have stimulated production and competition and competition always controls the price, and this is shown clearly by actual facts. For instance, on indigo and alizarine colors there is no duty, and as a consequence they are not made here. Theoretically, therefore, they should be sold very cheap, but as a matter of fact by reason of no competition here they are controlled by conventions in Europe which make a uniform price and consumers are, therefore, unquestionably paying more than they would have to pay if such products were made here in competition. On the other hand, take, for instance, direct cotton black, which is an aniline dye which has a protective duty of 30 per cent, and which is made in this country in large quantities, and on which the Europeans have been obliged to reduce their selling price in this country to less than they sell for in Europe, so that American consumers are enjoying prices as low as 17 to 18 cents for a color which sells at from 22 cents and upwards in Europe under normal conditions.

Does any one believe that the low prices would have been made in this country were it not for the competition here, and does it not therefore prove that competition here regulates the price and that it is not so much a question of duty? What the American manufacturers want is not so much a high duty as it is that they want enough to equalize the difference in manufacturing conditions between this country and Europe and protection against the so-called unfair competition referred to in my remarks in connection with aniline oil; in other words, the inclusion of the so-called "dumping" clause. With a proper tariff on these lines the business could be successfully developed.

I might say further that if we could get our intermediate materials at the same prices which are paid by the Germans, and then secure for our colors the same prices obtained by the Germans for finished colors in other countries, plus the actual American duty, the problem would be solved, as this actual American duty if sufficient would then cover our extra cost of manufacturing, and put us in the exact position as are the Germans as far as our selling prices are concerned.

Secondly, as to the modification of our patent laws, so that they would require the manufacture in the United States of all such articles for which patents are issued. England has within the past few years made such changes in her patent laws, and as for Germany, she has always required the manufacture of patented products in her own country. Her present law reads in general that the owner of a patent must work the invention to an adequate extent in this country (Germany) or at all events do all that is necessary to secure such working, and if he does not, then if the public interest is such that the granting of permission to others to use the invention appears needful, it is granted by making some arrangement with the owner of the patent so that he received adequate compensation, but the manufacture of the product itself is insured for Germany.

About 1909 a similar clause was threatened in the patent laws of this country, and to head off such action Germany negotiated a treaty with the United States by which the German working clause was made inoperative on American inventions. In other words, in return for the United States allowing Germany to continue to manufacture her products in Germany and export them to the United States, the United States was allowed a similar latitude in exporting her patented products into Germany. Whether or not the financial results of this treaty were beneficial to the United States is a question, but it certainly did not work out to the benefit of the United States as far as coal tar products are concerned.

In what I have already termed the golden period of the industry, viz., from 1880 onward, there was from 1880 to 1883 a duty of 35 per cent ad valorem and 50 cents per lb. specific, which gave ample protection to the industry, and as a consequence there were nine or ten factories in the United States, and the prospect of becoming independent of other nations for our supply of these aniline products was bright indeed, but the passage of the Tariff Act of July 1, 1883, which abolished the specific duty of 50 cents per lb., leaving only the ad valorem duty of 35 per cent and fixing a 20 per cent duty on the intermediate products, which left only a net protection of 15 per cent, immediately checked the industry here. No new factories were started, and within one year after the new tariff took effect five of those already established were forced to succumb and go out of business, leaving only four to continue the work. Those four would have gladly followed their example but had invested large sums of money in plants which would be an entire loss if abandoned. So they decided to continue to operate their factories, hoping for more favorable legislation in the future, but thus far they have always been bitterly disappointed. No tariff since that time has given them sufficient protection to develop the business to any large extent. Of course, a specific duty of 50 cents in those days was not abnormal, as the selling prices of the colors were so much higher than at present, and if a proper duty had been continued it would have had the same beneficial effect, but the abandonment of a sufficient duty has left open the admission of colors on a basis which really gives no protection at all.

In addition to the first or protective question as a stimulant to the creation of this industry in America, and coming to the second reason—the patent situation—if the Government had in the same golden period, viz., the eighties, required the manufacture in this country of all products for which they issued patents, then it would have at once created a large industry here. The European patentees would have been forced to build factories here to make these products. This means it would have resulted in branches of the European factories in this country, which would undoubtedly have developed into other products even though they might have originally only been erected for the manufacture of patented articles. While this would not have helped the then American factories it would at the same time have inevitably created a large industry here with beneficent results to the country at large.

As I have stated, there are now four factories in the United States manufacturing aniline dyes, our own factory having been established in 1879. While of slow development, at the same time it has been successful to the extent that it has kept in business and now manufactures practically all of the seventy-six different colors mentioned by Dr. Hesse, or, to be correct, the one hundred, to which I referred in the beginning of my remarks, these colors being all of the original colors, such as Bismarck brown, magenta, chrysoidine, fast red, water or soluble blues, eosines, nigrosines, a comprehensive line of direct dyeing cotton colors, and a comprehensive line of acid and chrome colors for wool and silk. This could easily be extended to the manufacture of practically all of the necessary colors now demanded, and which are not covered by patents, so giving the consumer a large variety to choose from, and insuring practical independence of Europe under any conditions. This would be a large business in itself, except by comparison with the great German factories which stand alone in their magnitude.

All of the American factories will continue to manufacture colors to the best of their ability, but they cannot promise any extensive increase in their production without the support of the Government in the line of tariff protection, and incidentally, the change in the patent laws. The latter, however, is not now quite so important as to colors for the reason that many of the original patents have expired and we are free to manufacture a large line of colors provided it is made commercially possible for us to do so, we having already demonstrated our ability to do so as far as experience and willingness are concerned.

I might mention, as far as our own factory in Buffalo is concerned, which by the way, is widely known as the "Schoellkopf Aniline Works," we were the pioneers in the manufacture of such products as nitrobenzol, nitro-toluole, binitro-toluole, binitro-benzol, aniline oil, aniline salts, dimethyl-aniline, and quite a range of sulfo-acids, some of them of our own invention, which are necessary for the manufacture of both acid and direct colors.

We have also made such products as pure carbolic acid and pure naphthaline, but were obliged to give them up as well as the others because we could not compete with the European manufacturers, but we are now hoping that they can again be taken up either by us or by possible manufacturers of intermediate products, and the manufacture continued successfully in this country.

Under the present abnormal conditions our factory is again making some of these products in order to keep in operation as just at present it is not a question of price, but of ability to manufacture aniline dyes almost no matter at what cost, such is the demand. But, whenever conditions become more normal again, then we will necessarily have to give up the manufacture of these intermediate products for the same reasons that we have had to give them up before, viz., that we can purchase them in Europe at lower prices than they can be manufactured here.

I might mention further that our factories in Buffalo are still controlled and directed by Mr. J. F. Schoellkopf, who originally established them, being assisted a little later by his brother, Mr. C. P. Hugo Schoellkopf, so that they have had nearly thirty-five years of continuous experience in the manufacture of aniline products, and are fully competent to continue the manufacture in a large way should conditions develop so they can be increased.

This paper is not intended to appeal for sympathy or help from the Government or from American consumers. We happen to be so placed for the past few years that we could not develop our business as it might have been developed under different conditions. The American factories even as they are, are prosperous, and quite able to take care of themselves up to a certain point. But this paper is intended to show that the business cannot be extended to large proportions for the protection of American consumers, unless with Government help as to tariff and patent laws, as well as the assistance of the consumers themselves, which means giving the American manufacturers the preference wherever they can do so and assisting them to secure the necessary help from the Government.

Here then is a superficial history of the progress of the aniline industry from its inception to the present time, not only in this country but in Europe, and the situation as related to the present and future manufacture of these products in the United States fully explained. Will the United States Government continue its indifferent policy of practically allowing this important industry to drift along as heretofore, or will it now wake up and seize the opportunity to make itself independent of all other nations in its supply of coal-tar products not only for aniline dyes for commercial purposes, but also for pharmaceutical products which relieve illness and pertain to the health of its inhabitants, and for products for the manufacture of explosives which would be absolutely vital in case of war. The future alone can answer these questions.[*]

## The Situation in the Chemical and Dyestuff Industry

The first regular meeting of the New York section of the American Chemical Society was held on the evening of October 9, the general subject of the evening being a conference on chemicals and dyestuffs.

Prof. Allen Rogers, the chairman of the section, referred in his introductory remarks to the European war and the changes which have taken place in the dyestuff industry. He discussed concisely the most salient points to be considered—some 14 points in all.

Dr. J. Merritt Matthews followed with a paper on dyestuffs in the textile industries. He gave a review of the use of dyestuffs and various dyestuff materials—dyewoods, cochinel, and asked and discussed at length the question: Why do we dye our clothes? He then took up the relative merits of aniline dyes versus vegetable and animal dyes. Aniline dyes are uniform, exactly reproducible, and free from foreign materials. Dyewood dyes are not so; 78 different dyes are used in the United States. Dr. Matthews discussed wool dyeing, cotton dyeing, silk dyeing, mordants, and outlined the remarkable career of alizarine dyes.

Mr. Arthur Brill, editor of the *Daily Trade Record*, Millman's Section, followed with a paper on the campaign for the American dyestuff industry. The *Trade Record* tried to help the American dye manufacturers and textile mills, but met with much opposition. There was a remarkable fear on the part of many of the manufacturers to tell the public the actual state of affairs. They preferred to advertise: "Our textile goods will not lack in quality on account of poor dyes. We have large quantities of the best imported dyes." Accordingly this bluff puzzled dye manufacturers. It is high time that people ought to get together and frankly admit actual facts. Textile mills complained to the *Trade Record* that any frank acknowledgement of the state of affairs would reduce and has reduced sales.

Mr. I. F. Stone, president of the National Aniline and Chemical Company, followed with a paper on coal tar colors in America. On account of Mr. Stone's position in the industry and the authoritiative character of his paper, we print his paper in full on page 679.

The last paper of the evening was presented by Mr. Alfred L. Lustig (chairman of the Dyestuff Committee, National Association of Finishers of Textile Cotton Fabrics): Needs of the textile industry.

He spoke briefly on various points, especially tariff regulation, and emphasized that it was very often plain prejudice if the quality of dyes made in the United States was not considered equal to German dyes.

The attendance was very large, every seat in Rumford Hall being taken. A lively discussion was probably expected by many, but did not materialize. The discussion was short.

To sum up concisely the gist of the discussion of the evening:—The United States makes a limited quantity of dyes and small numbers of shades. There is a general uncertainty as to the duration of the war, as to new tariff legislation, etc. This holds back new undertakings. Americans refrain from enlarging their plants and introducing new processes, until a certain amount of assurance can be given that the enlarged industry will be protected in some way or other. There is no doubt that the aniline dyes are much better than dyewood products.

## Chemistry in Lighting

The first meeting of the season of the New York section of the American Electrochemical Society, of which Dr. Colin G. Fink, of the General Electric Lamp Works, Harrison, N. J., is the chairman, will be held at the Chemists' Club, 50 East Forty-first Street, New York City, November 10, 1914. The meeting will be held by the New York section of the American Electrochemical Society with the co-operation of the American Gas Institute and the New York section of the Illuminating Engineering Society. The general subject of the evening will be the effect of chemical research on lighting.

A most interesting program has been prepared, as follows:

Dr. C. G. Fink:—Introductory remarks.

Professor M. C. Whitaker (of Columbia University, New York):—Improvements in the incandescent mantle.

Dr. William C. Moore (National Carbon Co., Cleveland):—Chemistry in the development and operation of flaming-arc lamps.

Dr. R. E. Meyers (Westinghouse Lamp Company, Bloomfield, N. J.):—The new tungsten lamps.

Mr. R. D. Bailey (Cooper-Hewitt Electric Company, Hoboken, N. J.):—The quartz-tube mercury-vapor lamp and its applications in chemistry.

Mr. D. McFarlan Moore (General Electric Company, Harrison, N. J.):—The new Moore tube lamps and the neon tube lamps.

Dr. Herbert E. Ives (United Gas Improvement Company, Philadelphia, Pa.):—The light of the future.

**Arizona Copper Co.** has reduced its production of copper in common with most other western producers. The output for August was 1869 tons of copper, but the September production will be lower.

**Link-Belt Locomotive Cranes** is the title of bulletin 158, just issued by the Link-Belt Company, of Chicago, Philadelphia and Indianapolis. The numerous excellent illustrations show the very large extent to which locomotive cranes are now used in the art of handling materials in the most varied industries. In the one machine is combined a portable hoisting engine, swinging derrick, grab bucket unloader and switch engine. The photographs from practice in various prominent fuel and iron and steel plants are particularly interesting. The chemical industries are represented by illustrations of locomotive crane practice of the Solvay Process Company, the Michigan Alkali Company and various sugar plants.

---

[*] *Addendum.*—After reading this paper, in reply to a question as to whether or not any original work had been done by the American dye manufacturers, that is, whether they had discovered any new products, Mr. Stone stated that sixteen patents had been taken out by the Schoellkopf Works between 1884 and 1903, comprising colors and intermediate products. One of these products, known as Schoellkopf acid, had been taken up by one of the largest German manufacturers and used extensively by them. Another product, direct black, had been taken up by another large German factory and also made extensively by them. Both products were used, of course, through arrangements with the Schoellkopf Works. So the question could be answered in the affirmative.

# The Gas from Blast Furnaces, Its Cleaning and Utilization

BY J. E. JOHNSON, JR.

The realization of the great heating value of the top gases of the blast furnace was very slow in taking useful shape. For centuries, furnaces ran with their tops wide open, discharging the gas into the air, with which it united in a great column of flame, visible for miles by night, even in the smaller furnaces of that early day.

Even after the invention of the steam engine, the possibilities of blowing furnaces by steam power were not practically realized for several decades and furnaces continued to be located primarily with reference to a suitable water power for blowing. In the same way after the invention of the hot-blast in the third decade of the nineteenth century the stoves were not at first heated by gas from the furnace, but were independently fired with coal.

Later a small chamber filled with iron pipes was built over the top of the furnace and the flame from the open top passed up through this, heating the blast which passed through the pipes. Still later flues were built into the brick work near the top, but just below the stock line and connected with a powerful chimney whose base was approximately level with the top of the furnace, this chimney drew some of the gas from the furnace, naturally much mixed with air drawn in from above, and the mixture burnt on its passage from the furnace top through the boilers and stoves to the chimney.

The final step was taken by closing the top of the furnace with a huge conical valve called the "bell" and forcing the gas by the pressure from below out through the flues into a pipe leading down to the ground level, where the stoves, boilers and stacks were located. This pipe early received and still retains the name of the "down-comer."

These top gases in Lake ore practice contain about 50 per cent of the total thermal value of the fuel charged. In districts where leaner ores are used and more fuel is consequently required per ton of iron the gas is correspondingly richer and contains a proportionately larger percentage of the thermal value of the fuel. In Lake ore practice an average analysis is about as follows: carbon monoxide 25½ per cent, hydrogen 3 per cent, carbon dioxide 12½ per cent, nitrogen 59 per cent. The thermal value comes entirely from the two former components.

The hydrogen comes partly from the moisture in the blast which is dissociated in the hearth, and partly from the moisture of the charge which is decomposed in the upper levels of the furnace. This gas under standard conditions of 32 deg. F. and 30 inches of mercury contains from 94 to 102 B.t.u. per cubic foot and has a specific heat of about 0.02 per cubic foot so that it contains about 2 B.t.u. of sensible heat for each 100 deg. F. above that temperature.

This gas is then somewhat more than half as high in heating value per cubic foot as ordinary producer gas. This with the enormous volume produced (some 140,000 cu. ft. per ton of iron in good practice and more where the practice is poorer) give it enormous commercial value, so great in fact as to equal a considerable percentage of that of the pig-iron itself.

This gas having been in intimate contact with the charge in its course up through the furnace, and having carried off all the moisture of the charge not dissociated, necessarily contains much moisture and picks up much fine dust from all the different components of the charge. It also carries a fume consisting of solids volatilized in the hearth of the furnace which sublime into the solid state, but in the form of an impalpable powder, as the gas cools in its progress toward the furnace top.

It is this fume that gives the gas its characteristic appearance, so that an experienced furnaceman can tell more quickly by looking at the gas discharging from the boiler and stove stacks than by any other way if his furnace is working "hot" or "cold," since a relatively few degrees drop in hearth temperature make a great difference in the amount and appearance of the fume thrown off.

The composition of this fume will be treated more at length in a subsequent article; for the present it is only necessary to say that it consists mainly of silica, alumina, lime, potash from the ash of the coke, and iron, and in case the charge contains much manganese, this element is present in the fume to a great extent, changing the white color of the fume of a good working furnace on ordinary iron to a light yellow when running on "spiegel" and to a dark yellow or brown when running on ferromanganese.

In the early days of slow driving the velocity of the gas current through the furnace was small and the quantity of fine ore in the charge was almost negligible in comparison with the quantity of fine ore used to-day, which runs from 50 to 100 per cent Mesabi in the majority of American practice.

Under those conditions a single, comparatively small outlet at one side of the furnace top was sufficient and the quantity of dust carried by the gas was extremely small, therefore a single pipe of moderate size running straight or almost straight down and branching directly off to the stoves and boilers was all that was necessary to handle the gas. This constituted but a small, almost an insignificant fraction of the plant as a whole. Conditions at the present are vastly different from this in three respects:

First, the velocity of the gas through the furnace is several times greater than it was in those early days and the carrying power of the fluid current increases at an enormously rapid rate with an increase in velocity. I have seen the statement that this increase was as the seventh power, which would mean that doubling the velocity would increase the quantity of material carried 128 times. Whether this be true or not it is certain that the rate of increase in carrying power is extremely high.

Second, the ore used instead of being practically all hand-prepared lump consists very largely of fines, much of which is capable of passing through a 100-mesh sieve.

Third, we have come to realize the enormous cost of attempting to utilize gas in its dirty condition for stoves and boilers, even leaving out of consideration gas engines which require gas cleaner than the air we breathe for their successful operation.

These three causes have had an enormous effect on the gas-handling system of the furnace which has in recent years become one of the largest and most conspicuous features of the whole blast furnace plant.

## The Outlets from the Furnace Top

From the time of the closed top or soon thereafter, some furnacemen claimed that the gas should be taken off either from the center of the furnace or at several points symmetrically arranged around the furnace top. Others claimed that the gas, having gone through the stock column, had done its work and that the location of the outlet was a matter of no importance, and that one large outlet located on one side was cheaper and simpler than any other arrangement and just as good.

In connection with furnace tops, I shall show a design of top arranged to take the gas out at the center.

which worked successfully for many years and gave but little trouble. It was, however, impossible to make the top quite so simple in this way as with the outlet on one side, and so the great majority of furnaces built in the United States up to twenty years ago were constructed on the latter plan, although in discussing operation I shall show what is to my mind an indisputable proof that a single side outlet produces an unsymmetrical passage of the gas through the furnace and cannot lead to the best work.

As furnaces and their outputs grew they produced a vastly larger quantity of gas, so their designers provided more gas outlets, two and even up to five or six. Good practice now very generally uses four, though in my judgment three properly located are sufficient.

### Downcomers

This introduction of multiple outlets introduced other difficulties into the design of the plant.

With a single outlet the down-comer could drop almost vertically to the ground close to the base of the furnace, but with this growth of output, necessitating multiple outlets, came the vast increase of dust which I have mentioned and the necessity for providing some means for its removal. As long as the gas traveled on a steep downward slope the dust would accompany it, but when the dust reached the horizontal passages leading to the stoves and boilers and from these to the stack it settled in them and obstructed them so rapidly as to constitute a serious obstacle to continuous and satisfactory operation.

Means therefore had to be provided for the removal of the dust at the foot of the down-comer and for this purpose chambers, at first only a little larger than the gas mains were introduced, but as conditions grew worse and worse these were increased in size and required therefore to be placed further from the furnace in order to give the necessary room for operation.

This threw the foot of the down-comer away from the furnace at its base, while the necessity of reaching more than one outlet threw its top back, from the closest point on the top of the furnace shell, to the center line of the shell when two outlets were used, and finally to the back or opposite side when four or more were used. These two factors flattened the slope of the down-comer from almost vertical to a slope well below 45 deg.

In some of the earlier installations these conditions were made still worse because it was considered necessary to have the down-comer enter the top of the dust-catcher in the center of the latter and this reduced the vertical height at the same time all the other factors above mentioned increased its horizontal reach. I think that the slope of the dust-catcher on some of the plants built about the time of the Duquesne revolution was not more than 30 deg. These were extremely unsatisfactory in operation because not only would dust lodge in them but also coke and other materials from the charge; they did not free themselves under any circumstances and no matter how large they might be built they filled up until the velocity of the gas through them was great enough to scour a passageway through the accumulation on the bottom slope, this of course involving high top pressure and consequent leakage on every joint not tightly sealed.

### Explosion Doors

Down-comers are generally provided with explosion doors for two purposes: First, when furnaces are stopped it is almost impossible to prevent air being drawn into the gas main at some point or other. This air mixes with the gas and produces an explosive mixture. When operation is resumed this mixture is ignited at the boiler or stove burners and an explosion follows which in some cases is violent enough to burst the main, dust-catcher and down-comer unless it is relieved by suitable safety-valves or explosion doors.

Second, the furnace itself is liable to slips or explosions in which a pressure of several pounds to the square inch, ordinarily only occurring at the lower levels of the furnace reaches the top and would do it great damage unless properly relieved.

This later theory has been combatted by Mr. Julian Kennedy who has claimed that explosions were more violent in proportion as they received freer vent; comparing the conditions which arise at such times to those occurring when the cork is removed from a bottle of charged water, if this be done suddenly a great proportion of the contents of the bottle is violently ejected, but if the cork is held back and the gas pressure allowed to pass off slowly none of the contents of the bottle are thrown out. In accordance with this theory the tendency in recent years has been to provide many less explosion-doors than were formerly thought to be necessary, and the results have very largely confirmed the theory, though many furnacemen are not willing to go as far as advocated by Mr. Kennedy and do away with explosion doors entirely.

One design, made about the time of the Duquesne revolution, was intended to be the best possible regardless of expense. Some five or six outlets were provided around the top of the furnace and these were all connected with an annular main, from one or two points on which the branches of the down-comer led off. Explosion doors were arranged on the outside of this annular main, which, of course, was a few feet below the operating platform of the furnace top and in order to provide access to it a supplementary platform was built a few feet below.

This system had almost all of the disadvantages which could be worked into one design. On the side opposite to the down-comer there was so little current of gas that the annular main became sufficiently choked up to make it virtually useless and one or two outlets on the side next to the down-comer carried off all the gas, practically as though the annular main did not exist. On account of the large size and distant location of the dust-catcher and the wide stretch of its branches to reach the opposite sides of the annular gas main the slope of the down-comer was exceedingly flat and it is probable that after it was in operation a short time more than half its area was choked up and not in active use. One of the worst features of the design was the location of the explosion doors which, it will be seen, came just under the main operating platform. Owing to the choked condition of the down-comer the top pressure was high and the explosion doors were generally leaking more or less; if the gas caught fire it burnt underneath the top platform so as to damage the steel work, and if it escaped unburnt the gas came up onto the top platform in sufficient quantity to make it dangerous to stay there any considerable length of time.

It may not be amiss to say a word here as to the general design of explosion doors. These are always made hinged, but are located in two different ways; first, so that the plane of the door is horizontal when closed; second, so that it is steeply inclined or vertical when closed. The latter design is radically wrong and should never be used because the moment of the door due to its weight is little or nothing when it hangs vertical, consequently a slight pressure is sufficient to force it from its seat, but as its moment rapidly increases a much greater pressure is required to force it to open wide as it should when it is needed at all.

The horizontal door works exactly the opposite way exerting its maximum moment when it is closed so that it is very easy to keep tight under ordinary conditions. But when a considerable increase of pressure occurs, forcing the door open to relieve it, the moment of the door decreases as it opens so that it operates more and more easily as it opens wider. This seems at first sight to be an insignificant detail, but as a matter of fact I have seen great annoyances caused by vertical doors, so little gas leaking from them can be objectionable either by burning and damaging the structure or by polluting the air, that the final result is to have a rigid clamp put on the door which virtually destroys its usefulness for its primary purpose even though it may not completely eliminate the leakage.

Fig. 1 shows a design of gas outlets and down-comer which secures practically all the important advantages. The drawing shows the "E" furnace of the Bethlehem Steel Company. The outlets are four in number rising from the conical top of the furnace shell. The down-comer instead of connecting directly with the outlet openings on the furnace shell on the back or high side connects with the outlet pipes at a point several feet above the operating platform and thereby secures sufficient height to give it a slope steep enough to free itself. The explosion doors are placed on the top of these high outlet pipes many feet above the operating platform and if they leak no harm is done. If the gas burns it cannot strike anything to destroy and if it remains unburnt it pollutes the air far above the heads of those who may have occasion to be upon the operating platform.

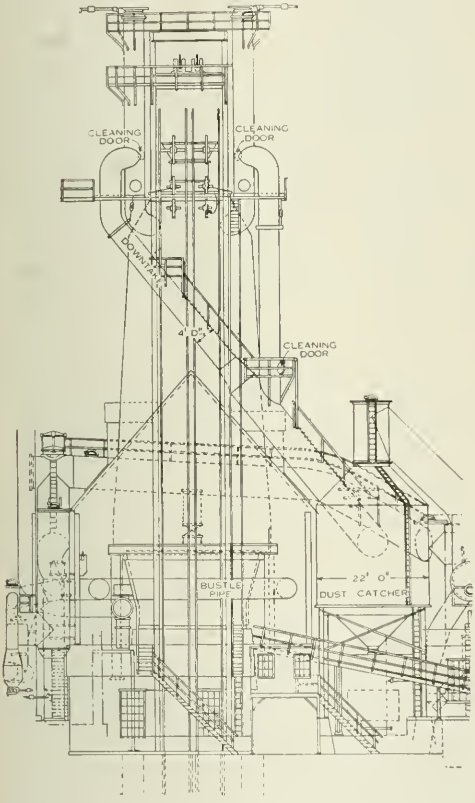

FIG. 1—ELEVATION OF BETHLEHEM STEEL CO.'S FURNACE SHOWING CORRECT DESIGN OF GAS OUTLETS

In the early days the down-comers were made of quite thin pipe entirely unlined and these gave remarkably good service considering the relatively high temperature of the gas they sometimes had to handle, temperatures of 800 or even 1000 deg. F. in regular operation being not uncommon, while, of course, very much higher ones occurred during slips.

In modern practice, however, the down-comer is always built of very substantial steel plate and lined with circle bricks from 3 to 4½ in. thick. This makes an almost indestructible construction but a very heavy one so that due care must be taken to support the weight of the down-comer at both ends. More than one case is on record in which no better support had been provided than the conical top of the dust catcher and this has buckled under the great weight thrown upon it.

### Dust-Catchers

Dust-catchers were not considered a necessary part of a plant until within the last twenty or twenty-five years. The first ones were crudely designed, simply with the idea of providing an enlargement in the gas main in which the velocity of the gas would be reduced and its dust contents dropped to the bottom by this reduction in velocity. Ordinarily very inadequate means were provided to prevent the gas current from picking up again the dust it had once deposited, and the efficiency of the apparatus was in some cases so low that the quantity of dust recovered was inappreciable, and after several years trial the dust-catcher was thrown out and replaced by a plain section of pipe. Evenually the idea took shape of combining centrifugal force with the reduction in velocity to throw out the dust.

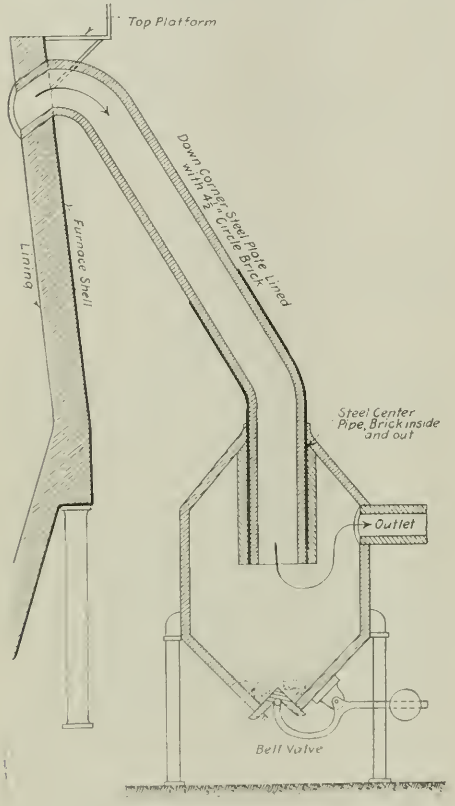
The sketch, Fig. 2, illustrates diagrammatically the construction which came to be standard for the first type. Fig. 3 shows an early type sometimes used to secure the centrifugal effect. The tangential inlet into the dust-catcher body constitutes the principal difference in the two types.

The difficulty of preventing the dust from being picked up by the gas current after being once deposited was a serious one and its solution was sought by several furnacemen and several designs were brought out to overcome it by having the dust impinge upon the surface of water to which it would adhere and from which the gas could not pick it up again.

One of the earliest designs to embody this principle was that of Mr. F. E. Bachman, then manager of the Northern Iron Company, at Port Henry, N. Y. Mr. Bachman built a dust-catcher in general appearance not differing greatly from the ordinary type provided with a tangential inlet as shown in Fig. 3. The shell of this instead of being lined with firebrick, as in ordinary constructions, was sprayed inside with a great number of small jets of water which produced a water film running down over this whole interior surface. Centrifugal force threw the gas against this surface to which the dust adhered and was carried to the bottom by the flow of the water film. The gas only being exposed to the surface of the water for a short time did not absorb enough water vapor to affect its thermal value materially. This dust-catcher was in operation for a number of years (as far as known to me it still is) and gave excellent results. The stoves remained clean and serviceable, although the furnace was charged exclusively with magnetic concentrates, which were quite fine.

Another design to secure this result was that of Mr. R. C. Steece, whose dust-catcher is shown by Fig. 4.

The body of the dust-catcher is horizontal and filled with water to about one-third of its height. The gas enters at one end so as to impinge on the surface of the water and is reflected therefrom into a semi-circular passage which brings it back to impinge upon the water a second time. A second semi-circular passage repeats the operation once more and the gas is finally discharged at the far end of the dust-catcher.



Top Platform
Down Corner, Steel plate Lined with 4½" Circle Brick
Lining
Furnace Shell
Steel Center Pipe, Brick inside and out
Outlet
Bell Valve

FIG. 2—TYPICAL FORM OF EARLY DUST CATCHER

This design avoids the maintenance of the sprays required by the Bachman apparatus, but, on the other hand, the surface of the water is not constantly and rapidly renewed as it is in the Bachman design and this is a point of much importance because when the surface of the water becomes fouled by a heavy layer of dust, other dust impinging upon this is not held but liable to be picked up again and carried on by the gas.

Another dust-catcher which uses the principle of having the gas impinge upon the surface of water is the invention of Mr. B. F. Mullen, of Leetonia, Ohio. This dust-catcher has had the widest appliance of any apparatus of its type. The design is shown in Fig. 4a. The external shape of the apparatus is not unlike that of the standard dust-catcher. The gas enters at the top and passes into the central chamber shown. This chamber is suspended from the dome of the dust-catcher, its shell is lined with firebrick and its bottom constitutes a tube plate supported by the suspension rods *L*. Through the tube plate project a great number of short tubes through which the gas is forced to pass at a considerable velocity. The bottom cone of the apparatus is filled with water to a level from 4 in. to 6 in. below the bottom of the tubes. This level is maintained by overflow through the ports *H* around the circumference of the dust-catcher body.

Fresh water is introduced into the center through the pipe shown and flows regularly outward to the outlet ports *H* through which it discharges. This keeps the surface of the water constantly in motion and prevents its becoming too foul to hold the dirt thrown upon it.

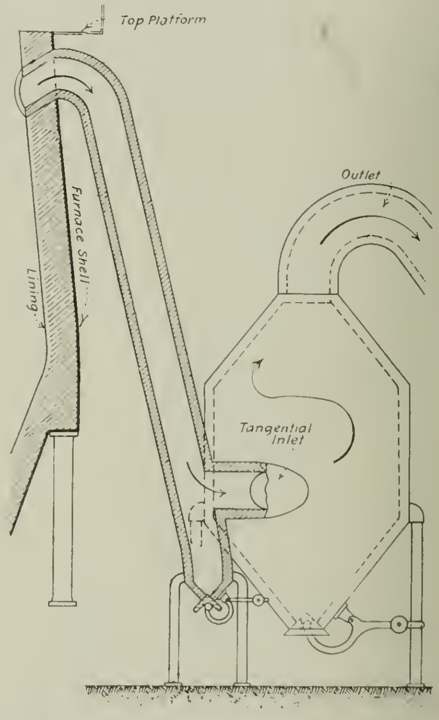


FIG. 3—TYPICAL FORM OF CENTRIFUGAL DUST CATCHER

After the gas leaves the tubes and impinges upon the water surface it passes into the annular space around the central chamber and so to the outlet at the side. The top of the outlet trough just beneath the ports *H* is sealed by a conical plate the bottom of which is riveted to the bottom of the trough, while its top is riveted to the shell of the dust-catcher proper.

The light dust which lodges on the surface of the water is carried away by the flow of the water, while the heavy dust which penetrates the surface is flushed off from time to time through the bell valve at the bottom of the cone. A later design is modified so that the outlet trough for the waste water is inside the main dust-catcher structure instead of outside of it, but the principle remains the same.

This dust-catcher has given very good satisfaction in use. The principal point to be guarded against is any fluctuation of the water level which will permit the end of the discharge nozzles to become wet, because, if they do so the dust will rapidly build upon them and in time they will become completely obstructed. A fact not generally recognized is that flue dust has a very cement-like quality and that when dampened it sets almost as hard as a good cement. This fact has proven the destruction of the number of wet dust-catchers whose designers did not know how to provide against this difficulty.

Through the courtesy of the representative of the Mullen washer I have obtained a copy of the results of a test made on one of these washers by the superintendent of one of the largest blast furnace plants in the country, with a view to finding out if the apparatus were suitable for the conditions at his plant. The results of this test showed that the gas leaving the dust-catcher contained 2.28 grains per cubic foot of dust and after leaving the gas washer it contained 0.75. The representative of the gas washer claims that it is capable of doing considerably better work than this, but even this reduces to a third the total amount of dust carried into the stoves and boilers, as there is a very considerable proportion of the total dust carried through by the stack gases without being deposited, this reduces the proportion which lodges in the stoves and boilers, to their detriment, by a considerably greater percentage, and at the original plant where this washer was installed at Leetonia, Ohio, experience proved that they could run the stoves for the whole blast without taking them off the furnace for cleaning, which would be quite impossible without some means for reducing the dust in the gas far below the percentage which it contains on leaving the dust-catcher.

Many other types of dust-catchers have been built and tried out, but these described give the broad outlines of the art as it existed before the introduction of the gas engine. This forced a further step and a very long one in the direction of cleaning the gas, and as has so often happened, knowledge of the subject gained in learning to clean gas for gas engines has proven of great advantage in directions not contemplated when the work was undertaken. There seem to be definite limits to the degree to which the gas could be cleaned by any type of dust-catcher which depends upon gravity, centrifugal force, or impact upon the water surface or combination of any of these. The degree of cleanness so obtainable is barely sufficient for moderately good practice with the stoves, and as I have previously explained, great economies were effected by cleaning the gas a step beyond this point for use with stoves.

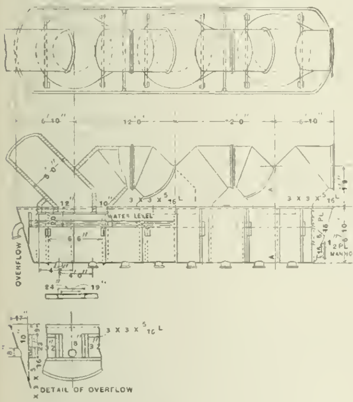

FIG. 4—STEESE AND FORD GAS WASHER

Most of the process used for the next step in cleaning have involved scrubbing the gas with water and this introduced another element in the situation. The gas as scrubbed picks up water vapor enough to saturate itself at the temperature at which it leaves the scrubber and this has a somewhat complicated effect. The gas as it comes from the furnace at a temperature of 300 deg. to 500 deg. carries a very considerable quantity of water vapor picked up from the stock which in a large proportion of modern practice is heavily sprayed with water just before being charged into the furnace. This water vapor is somewhat of a detriment to the gas since it acts as ballast during combustion and prevents attainment of as high a temperature as would be reached with the same gas at the same temperature, dry. By scrubbing the gas with water this temperature is reduced and its saturation point is so much lowered that water may actually be removed from it instead of being imparted by the scrubbing operation.

It is obvious that we have here two conflicting effects. The reduction of the temperature of the gas itself is bad because the sensible heat is an appreciable percentage of the total and if this is removed by any means before gas reaches the burners such removal represents an absolute loss. On the other hand, hot gas can carry an enormous amount of water vapor and this moisture going through the system acts as a damper on the combustion and prevents the temperature from rising as high as it otherwise would. Therefore, to remove the moisture is in itself a benefit.

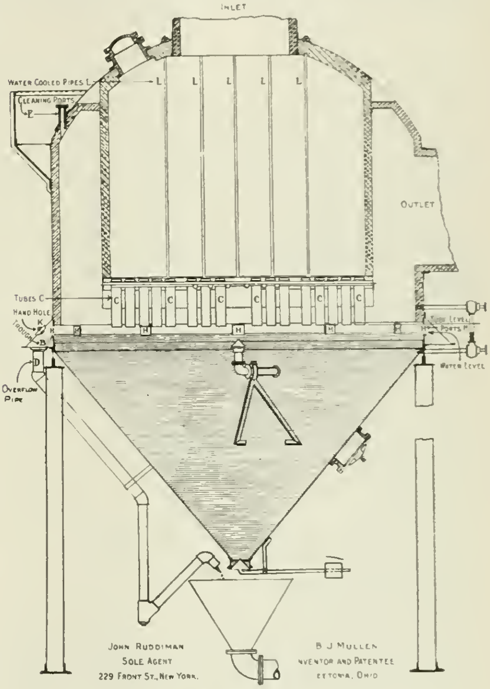

FIG. 4A—MULLEN GAS WASHER

There has been a certain amount of misapprehension on this subject. There have been in recent months two papers on the subject of gas cleaning, of which jointly the value probably exceeds anything published in English previous to that time. These are the papers of Mr. W. A. Forbes, "The Cleaning of the Blast Furnace Gas" before the October, 1913, meeting of the American Institute of Mining Engineers, and that of Mr. A. N. Diehl at the February, 1914, meeting of the same Institute entitled "Data Pertaining to the Gas Cleaning at the Duquesne Blast Furnaces."

From the former of these I shall presently quote extensively and from the latter also to a considerable ex-

TABLE 1.— HEAT AVAILABLE PER POUND OF DRY BLAST-FURNACE GAS UNDER VARIOUS CONDITIONS OF INITIAL TEMPERATURE AND MOISTURE CONTENT. COMBUSTION AIR CONSTANT CONDITION.

tent, but both of these in my judgment give an erroneous idea as to the relative importance of removing moisture and of cooling gas. Table 2 of Mr. Diehl's paper is reproduced here as Table 1.

It will be seen that he gives calculations showing the amount of heat obtainable per cubic foot of gas under three conditions.

First—Washed and cooled to 70 deg. Fahr. and saturated at that temperature with water vapor.

Second—Washed and cooled 125 deg. Fahr. and saturated at that temperature.

Third—Unwashed at 400 deg. Fahr. and containing 35 grains of moisture per cubic foot; in other words, its natural condition as it comes from the furnace.

Three temperatures for the escaping products of combustion from the stack 400 deg. Fahr., 500 deg. Fahr. and 600 deg. Fahr., are taken for each of the three cases.

Turning now to the third line from the bottom, "Total heat obtained per pound of dry gas consumed," it will be seen that the amounts in the three cases, all at 500 deg. stack temperature are 1076.6 B.t.u. for the first, 1088.43 for the second and 1166.49 for the third. It is obvious that the most available heat is to be obtained with hot gas in spite of high content of moisture.

Mr. Diehl gives a percentage figure for the three cases in the second line from the bottom of 83.23 per cent, 78.4 per cent and 80.31 per cent. Based on these percentages he states that the dry cold gas gives the highest percentage of available heat.

This is obviously incorrect, as the highest percentage must plainly coincide with the largest absolute amount of heat obtained on any correct basis of figuring. The error has arisen by counting as available the latent heat of vaporization of the water vapor in the gas in all cases. But this is in fact not available under any known conditions of boiler or stove operation since it would require gases to be cooled far below 212 deg. to precipitate much of this moisture and recover its latent heat.

It is obvious that if the burnt gas comes in at 400 deg. and goes out of the stack at 400 deg. no loss whatever has occurred, while if it goes out at 500 deg. or 600 deg., the only loss is that in superheating this small quantity of steam 35 grains, or 0.005 lb., of water vapor, with a specific heat of 0.48 through a range of 100 deg. or 200 deg., making a loss per cubic foot of gas of only a fraction of one thermal unit.

In regard to the effect on the combustion temperature, the results are similar. The quantity of air required for combustion is about equal in weight to the gas itself, therefore the reduction of the initial temperature of the gas by a given amount results in a reduction of the temperature combustion by about one-half of that amount; to cool the gas from 400 deg. Fahr. down to 70 therefore reduces the theoretical combustion temperature by about 160 deg. The removal of the moisture tends to raise the theoretical combustion temperature but quantitatively the amount of increase is smaller than the decrease due to the loss of sensible heat of the gas, about 100 deg. against 160 deg.

When the gas comes from a furnace which does not work a wet burden of ore or wet fuel the conditions become very much worse for wet scrubbing, because in that case there is but little moisture in the gas to be removed by a reduction of the temperature and therefore such reduction represents a net loss both of combustion temperature and of thermal efficiency due to lower combustion temperature.

In the discussion of the paper of Mr. Forbes above mentioned, it was stated by Mr. S. K. Varnes, of the Pennsylvania Steel Company, that at their furnaces they had introduced gas washers for the stoves but that they had been forced to abandon them because of the increased moisture and decreased temperature of the gas which resulted in a decided lowering of the combustion temperature and corresponding reduction of the blast temperature that could be obtained from the stoves. On the other hand, great benefit has been derived from wet scrubbing, where wet ore is used. Thus it will be seen that each case must be handled on its merits. Clean gas is always desirable and undoubtedly much cleaner gas will be used in stoves and boilers than we have been accustomed to in the past, but wet scrubbing should only be adopted after the most careful analysis of the conditions to see whether the net results will be beneficial or not, and if so, to what extent. There is but little use in supplying stoves with clean gas and then finding that we can get from them only lower blast temperatures than we could with dirty gas.

With this introduction I cannot do better than quote extensively from Mr. Forbes' paper as follows:

### DUST CONTENT IN GAS

The gas leaving the usual dust catcher contains an average of from 3 to 4 grains of dust per cubic foot, and its further cleaning is accomplished in one or two principal stages, depending on the ultimate use of the gas; namely, primary cleaning and final cleaning. In primary cleaning, the gas is sufficiently cleaned for economical use in heating hot-blast stoves and for raising steam in boilers; it has been found that the best results are obtained when the dust content of the gas, after cleaning, does not exceed 0.2 grain per cubic foot. In final cleaning, the gas is sufficiently cleaned for use in gas engines, and in this case the best practice has resulted when the dust content of the gas, after cleaning, does not exceed 0.008 grain per cubic foot.

Various systems and methods are employed for accomplishing the desired results. In modern practice, the gas leaving the blast furnace is, in practically all cases, conducted through downcomer mains and then through a dust catcher of large capacity, and in some cases through two such dust catchers in series. A considerable proportion of the heavier dust is deposited at this stage. From the dust catcher the gas passes to the additional cleaning apparatus through gas mains, usually equipped with downtakes and valves for the removal of the deposited dust. The mode of treatment from this point on varies considerably, according to the opinions of the operators as to the respective merits of various systems.

### PRIMARY DRY CLEANING

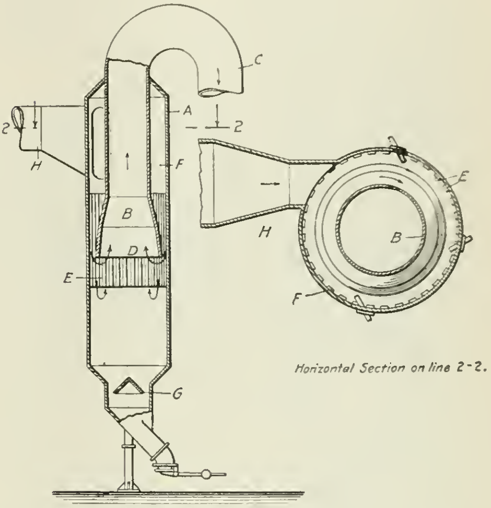
For primary cleaning, a separation of the dust without the use of water—in other words, dry cleaning—has been in favor at many plants on account of the ability to thus conserve the sensible heat of the gas, which is lost when water is used. The fact, however, should not be lost sight of that the benefit derived from the sensible heat of the dry-cleaned gas is largely discounted by the amount of water vapor in the gas. This is especially the case with gas from blast furnaces operating with a high top temperature and using ores and coke containing much moisture existing either free or chemically combined; the water vapor affects the efficiency of the combustion of the gas.

An additional benefit of dry cleaning lies in the greater facility to recover and handle the flue dust in the dry state than in the form of mud or slime in the wet cleaning processes. As before stated, the basic principles in practically all of these dry-cleaning systems depend upon a change in the direction of the gas, a reduction in its velocity, and the separation of the dust by gravity and centrifugal force. The various modifications by which this separation of dust is accomplished are all evolved from the so-called cyclone processes developed in Germany about 20 years ago. Some of these systems recently developed in the United States are the Brassert-Witting, the Roberts, the Kennedy, and the Dyblie. A description of the Brassert-Witting whirler and of the Dyblie whirler will illustrate the general principles of this type of cleaner.

### BRASSERT-WITTING WHIRLER

As shown in Figs. 5 and 6, the Brassert-Witting whirler consists of a vertical outer cylindrical casing, *A*, and an inner inverted tube, *B*, which at its upper end is integral with the gas main *C*, which takes the cleaned gas away from the apparatus. This inverted tube is flared at its lower end, *D*; a number of iron or steel bars, *E*, are fastened vertically around the chamber *F* and extend from a point well above the lower edge of the flared end *D* of the pipe to a point well below the lower edge of this pipe. In the lower part of the chamber *F* is placed a cone, *G*, which allows the separated dust to enter the outlet pipe.

The gas enters the apparatus tangentially through the flue *H* and is given a rotary whirling motion through the annular space between the pipe *B* and the wall of the chamber *A*. On coming in contact with the bars *E* the dust is caught in the channels between these bars and is held in position by the combined action of centrifugal force and friction. As the gas continues to rotate within the annular spaces above mentioned, its velocity is gradually increased by the action of the flared end of the receiving pipe until when it reaches the lower edge of the end its velocity is at a maximum. On passing below this edge, the velocity is constantly decreased, the direction of the gas is changed and it passes upwardly through the flared end of the pipe to the outgoing gas main *C*.



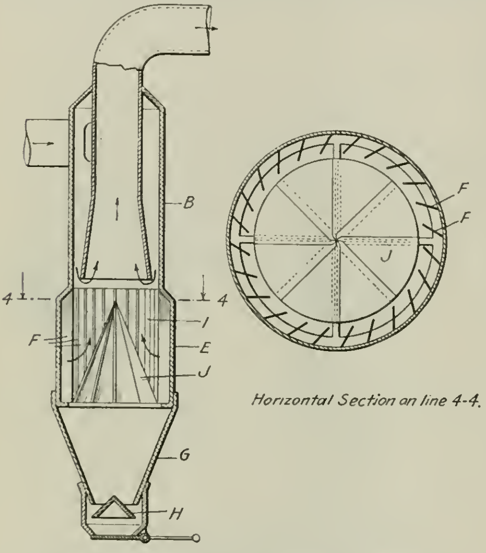
FIGS. 5 AND 6—VERTICAL AND HORIZONTAL SECTIONS OF BRASSERT-WITTING WHIRLER

The dust which has been caught in the channels between the baffle bars drops vertically into the bottom of the chamber, past the cone *G* and into the outlet pipe, whence it is removed as desired.

### BRASSERT MODIFICATIONS OF BRASSERT-WITTING WHIRLER

In the Brassert modifications of the Brassert-Witting whirler, a sketch of which is shown in Fig. 7, the lower portion of *E* of the casing is larger in diameter than the upper portion *B* and is provided with a series of inwardly projecting baffle plates, *F*. The lower portion *G* of the casing *E* is cone-shaped and constitutes the dust-receiving chamber. In the bottom of this chamber is a cone, *H*, whose function is to direct the dust toward the periphery of the dust outlet pipe. Within the chamber *I* another cone, *J*, is located and this cone is provided with a series of baffles, which are arranged as shown in Fig. 8.

In Fig. 9, which is a further modification, a spiral, *L*, is provided for the purpose of directing the flow of the gas. The lower end of the outlet pipe is made barrel-shaped. The outer casing *M* in its lower portion *N* is supplied with the baffles *O*, which instead of being mounted on the casing are bent inwardly therefrom, thus forming the apertures *P* (Fig. 10). The section *N* of the casing is inclosed by an outer casing, *Q*, thus forming the annular chamber *R*, in which partitions *S* are placed to prevent whirling of the gas in this annular chamber.



FIGS. 7 AND 8—VERTICAL AND HORIZONTAL SECTIONS OF BRASSERT MODIFICATION OF BRASSERT-WITTING WHIRLER

The gas is introduced and discharged and the dust is separated in a similar manner to that mentioned in the description of the Brassert-Witting whirler.

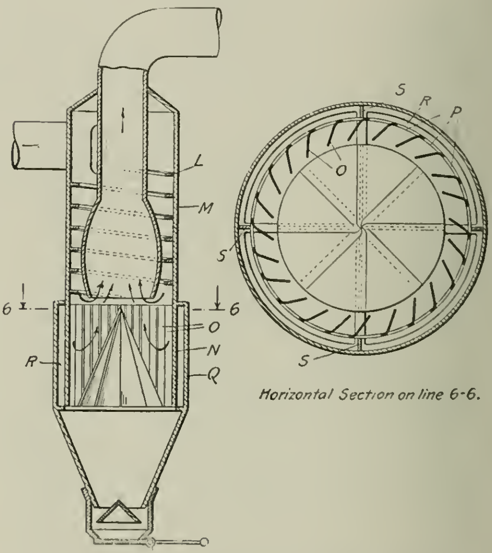
### DYBLIE WHIRLER

In this whirler, as in most of these types, the separation is accomplished by combined centrifugal force and the action of gravity. One of the principal features in this particular whirler is the arrangement in the spiral separator of the entrance and exit openings in substantially the same horizontal plane, obviating the necessity of the gas changing its direction of flow at a sharp angle.

Described in general terms, this separator consists of a spiral conduit, the lower open edges of which connect with the dust-collecting chamber. The gas is introduced tangentially and follows a spiral course toward the central axis of the apparatus, the spiral conduit being increased in area before the gas enters the central chamber, prior to its exit from the apparatus.

The dust is separated from the gas by centrifugal force and gravity, and falls through the lower open edges of the spiral into the dust-collecting chamber. The central chamber is provided with a small opening at its lower end, and connects with the innermost spiral of the spiral conduit.

In the accompanying sketches, Fig. 11 is a vertical section through the Dyblie whirler and Fig. 12 is a horizontal section. The gas enters tangentially from the gas main through the opening *A* in the shell of the casing; the gas impinges upon the first turn of the spiral *B* and follows the turns of the spiral. A separation of dust from the gas occurs through centrifugal force, the particles of greatest specific gravity being thrown outwardly and falling by gravity to the bottom of the casing. At the point *C*, an increased area is provided between the spiral and the central chamber, which causes a decrease in the velocity of the gas, thus allowing a further separation.



FIGS. 9 AND 10—VERTICAL AND HORIZONTAL SECTIONS OF BRASSERT MODIFICATION OF BRASSERT-WITTING WHIRLER

The inlet *A* and the outlet *D* are in substantially the same horizontal plane, and this permits the separated material to drop out of the whirling gas and prevents its being caught up in the vortex, which happens when a sudden change in the direction of the flow of the gas occurs.

A deflector, *E*, located at one edge of the opening, is provided. This is in the shape of a hook, which acts to catch any dust which might be carried into the casing, and this completes the separating operation.

### REMARKS ON EFFICIENCY OF DRY CLEANING

It has been demonstrated in practice that dry cleaning by anyone of the systems so far referred to, cannot be depended upon by itself to continuously clean the gas from blast furnaces using much fine ore, to the degree desired for use in stoves and under boilers, the amount of dust remaining in the gas ranging from 1 to 3 grains per cubic foot, depending on the working of the blast furnace. Such systems have a value, however, in removing, by simple apparatus and at practically no operating expense, a certain proportion of the dust and so decreasing the duty upon any apparatus installed for further cleaning.

The above remarks on dry cleaning refer in no way to the Halberger-Beth system, recently developed in Germany, which will be treated separately later on.

*(To be concluded.)*

# Quantitative Blowpiping as an Aid to the Prospector

BY SIEGFRIED FISCHER, JR.

## Introduction

It has been the writer's pleasure to attend one of the most interesting courses given in a metallurgical department of a university. At Lehigh University, South Bethlehem, Pa., Dr. Jos. W. Richards gives a course on quantitative blowpiping which to my knowledge is unique in this country. Its importance and value struck me at once, as it would be a godsend to the prospector. With some patience and good will the average scientifically educated prospector could become proficient in the manipulation of the operations so that he could save money which he now spends, in many cases uselessly, for having assays made on all materials which to him seem of value. But that is not the only saving.

When one wishes to make his own assays, a portable assaying outfit is necessary. This involves quite an expense and the outfit is not the easiest thing to transport from one place to another. When one realizes that the minimum apparatus necessary to perform an assay by means of a blowpipe analysis can be carried in a cigar box, and that its initial cost is about one-tenth of that of a portable assay equipment one can readily observe that there is a decided gain in its use.

The average prospector desires first of all to know whether or not his ore bears values such as gold and silver. Then if so, whether it is there in sufficient amounts to justify its working. The simplest quantitative blowpipe outfit will tell him that, if he is able to use it. With a more elaborate equipment he is enabled to attain results as close as any assayer. Such metals as gold, silver, copper, cobalt, nickel and mercury can be determined with a high degree of accuracy.

Dr. Richards has devised various means to simplify the work both in apparatus as well as in methods which I will describe in the course of this paper. My main endeavor in this article is to outline the methods used for the most important metals and to bring before mining institutions situated in localities where prospecting for these metals is carried on to-day, a course, which, if given in a summer school, would enable men outside of the institution, interested in prospecting work, to become more proficient in their field. As a course for metallurgical students it has another advantage, namely, that of performing metallurgical operations on a small scale.

With this outfit all work can be handled to show a prospector whether or not the ore he is considering is worthy of closer investigation or not. He can by this means save both money and time, as it always takes several days, and at times weeks and months, before he gets the "returns" from the assayer.

I have seen Dr. Richards complete a gold and silver assay in twenty minutes. Of course, he is an expert in this line of work, but the average working time which I have observed in the class was between one hour and one and one-half hours, the class numbering eight men. I myself have completed Au-AG-Cu assays within this time limit and a speiss containing Fe, Co, Ni, Cu, Au and Ag within two and one-half hours. Mercury ores can be easily finished in 10 minutes.

With a few additions to the equipment mentioned, we may check up our results or obtain greater accuracy. Greater accuracy may at times be attained by weighing theAu and Ag buttons. For this purpose a portable assay balance may be used. This increases the expense of the outfit, but it insures the correctness of the results. Such balances are of greater bulk, but there is no difficulty in devising means for combining these with the rest of the equipment into one unit. Such a balance may be had from one laboratory supply compound at a price of $70.00, being 8½ inch x 5 inch x 9½ inch in case, and having a sensitiveness of 1/100 milligram. Another balance furnished by the same company is the Nixon Portable Assay Balance; size 11 inch x 2 inch x 1 inch; cost, $20.00. Other firms have other makes, probably just as efficient as these.

GENERAL

Simple equipment.

| | | | |
|---|---|---|---|
| 1 | Pocket assay balance | $16.50 | $17.50 |
| 1 | Anvil | | 0.40 |
| 1 | Plattner's blow pipe, with removable platinum tip | | 2.50 |
| 1 | Charcoal borer | | 0.75 |
| | Natural charcoal, per 10 | | 50 |
| 1 | Set porcelain dishes | | 0.35 |
| 1 | Dropping bottle for nitric acid | | 0.15 |
| 1 | Plattner's platinum tipped forceps | | 2.00 |
| 1 | Form for paper cylinders | | 0.15 |
| 1 | Plattner hammer | | 0.60 |
| 1 | Ivory spoon | | 0.25 |
| 1 | Magnet | | 0.10 |
| 1 | Magnifying glass | | 1.50 |
| 1 | Agate mortar with pestle | | 1.70 |
| 1 | Mortar (Diamond Leed's) | | 2.00 |
| 1 | Pliers for buttons | | 0.75 |
| 1 | Plattner's ivory scale | | 3.00 |
| 1 | Alcohol lamp | $0.30- | 0.40 |
| 1 | Scissors | | 0.50 |
| 1 | Cupel holder with 2 molds and 1 stamp | | 1.70 |
| 1 | Test lead measure | | 0.50 |
| 6 | Small test tubes | | 0.12 |
| 1 | Horn scoop, small | | 0.25 |

Dr. Richards has devised a scale of alloys of gold and silver. These alloys are based on the percentage of silver in them, and the sample under investigation is compared with the colors of the alloys on the scale, one of which it will match. That will give the per cent of silver in the Au-Ag alloy and the rest is gold. This little button is usually flattened out on the anvil first, between two layers of filter paper to insure a bright surface. The accuracy is not very great, the silver content being given only for 1 per cent at a time and, as with all color comparisons, it depends on every individual's ability to match them. However, in many cases where absolute accuracy is not in question, this scale offers a very rapid and simple means to obtain approximately close results. A scale of this type contains thirty-six samples of gold-silver alloys, containing 0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 22, 24, 26, 28, 30, 32, 34, 36, 38, 40, 44, 48, 52, 56, 100 per cent of silver respectively.

Another apparatus of Dr. Richards' is his scale for measuring the buttons and obtaining the gold and silver. Two metal strips are fastened so that they touch at one end and diverge towards the other end. This forms a groove in which the button is rolled and measured. The right metal plate is graduated into 100 equal parts, and the groove is of such width that it gives the diameter of the button measured in one-hundredth of a millimeter. With this scale goes a table worked out by Dr. Richards himself, giving for each of the 100 divisions the weight of the gold button in milligrams, the weight of the silver button in milligrams, the volume of the button, the per cent Ag of the Au-Ag button, and the specific weight corresponding to the alloy. The use of this scale will be elucidated under the gold and silver assay.

With few exceptions, little need be said about the other apparatus in the equipment. However, it will pay to lay some stress on the Plattner ivory scale for the measurement of the gold and silver. It is constructed on the principle that buttons of silver or gold obtained by cupellation vary in size proportionally to their weight, and that these weights are proportional to one another and also proportional to the cubes of the diameters.

One is enabled to measure these diameters between two converging lines.

To get the scale Harkort and Plattner took the silver buttons of an ore, which on a muffle assay and a blowpipe assay showed 3.48 per cent Ag. They determined then the position of the best-formed button, obtained by cupellation, between the two converging lines, and this gave the division designated as 50. Dividing the stretch on the scale from the point at which the two lines meet to the point 50 into fifty equal parts, they obtained the left side of the scale. The convergence for a length of scale of 156 mm should be 0.09 mm. The right-hand figures give the per cent Ag by weight, if 100 mg of material were used for the assay.

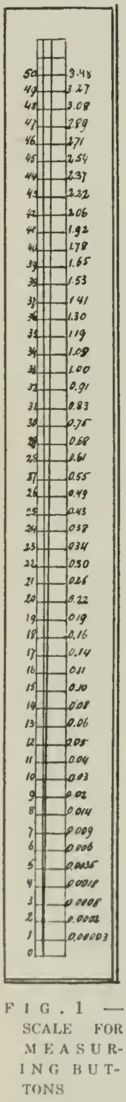

FIG. 1 — SCALE FOR MEASURING BUTTONS

Experience has shown that one can determine the weight of a silver button more accurately on the scale if it lies between 0 per cent and 0.45 per cent than it can be done on a balance. Above 0.45 per cent the balance is more accurate. Fig. 1 shows the Plattner scale.

To use this scale, the button obtained by cupellation is carefully cleaned. Care should be taken not to change its shape by any exertion of pressure, etc. It is then picked up in a pair of forceps, carefully put between the two converging lines and pushed along until both lines are just tangent to the edges of the button. To get correct readings one should use a magnifying glass. Repeated readings should be made. As the button is round great care must be taken in its handling, to prevent it from rolling off the scale and being lost. If the button lies between two of the horizontal divisions, the following should be observed: if it lies approximately half way between the two divisions, the numerical sum of these divided by 2 will give close enough results. If, however, the button is closer to one than the other one must then gauge by the eye.

As already mentioned, the numbers on the left-hand side of the scale give the weight in milligrams, if 1 decigram is used for the assay. If we now remember that there are 29,166 66/100 troy ounces in a ton of 2000 lb., and that in an assay ton = 450.09992 gr. troy there are 29,166 66/100 mg, then we see that if an assay ton were used for an assay, instead of 1 decigram, then each milligram of silver found would represent 1 oz. of metal per ton of ore.

Rule: To convert the milligram readings over into ounces divide the number of grains in an assay ton (450.09992) by the number of grains taken for the assay (where 1 decigram is used by 1.5432 grains); multiply the result by the weight of the button in milligrams according to the Plattner scale and the result is the number of ounces of silver the ore carries to the ton.

Example: Three grains of ore are taken for an assay. The silver button lies on division No. 16 equal to 0.11 mg.

Required: Number of ounces of silver to a ton of ore.

$$(450.09992 \div 3) \times 0.11 = 16.5 = 16\tfrac{1}{2} \text{ oz. of silver per ton.}$$

But not only is the Plattner scale of value for the silver determination, but Plattner himself has worked out the values for gold on the same scale, that is, the milligrams of gold for Division No. 0 to No. 26, which is the limiting division for accuracy. The best results obtained on this scale for gold are between 0 per cent and 0.45 Au.

PLATTNER SCALE FOR GOLD

| 2 | 0.0005 |
| 1 | 0.00006 |

Among the working tools of quantitative blowpiping, this scale and Dr. Richards' modification of it are without a doubt the most important ones and the correct manipulation is of paramount importance.

The other utensils may be found in any of the many catalogs of firms handling chemicals and laboratory apparatus and their use is self-evident.

One thing of great importance, which is not named in the equipment given is the soda paper. There is, however, no use spending money for it, as it can be very readily made in the following way: Cut strips of paper about 1 in. wide. Long ordinary bond paper is as good as any, the strips having the length of the sheet. Now prepare a saturated solution of sodium carbonate. Draw each strip through this solution so as to wet both sides along their entire length. Then hang them up to dry. When dry, cut these strips into pieces 1½ in. to 2 in. long and put into a covered box until required for use.

*Operations.* In quantitative blowpiping, the following steps must be observed:

I. Preparation of the ore for assaying.
    1. Grinding of a fair average sample.
    2. Sampling.
II. Weighing out sample.
III. Weighing out fluxes, etc.
IV. Making up the charge and wrapping it in soda paper.
V. Working down to the desired metal or metals. This step varies so much that each special case will be treated in detail under the individual metals.
VI. Determining the weight or percentage of the desired metal or metals.
    This will be taken up under the separate metals.

It will not be out of place here to mention some of the fundamental things. For quantitative work the luminous flame should be used, a flame such as a candle gives. Two kinds of flames may be obtained with this flame by using the blowpipe, the oxidizing and the reducing flame.

The oxidizing flame is obtained by putting the tip of the blowpipe into the flame and blowing rather strongly. The flame will be long, pointed and blue (Fig. 2). The harder the blowing the hotter the flame. The melting point of platinum, 1775 C., may be attained with it.

To produce a good reducing flame is more difficult than to produce a good oxidizing one. It is obtained by holding the tip of the blowpipe just outside of the flame and blowing not too strongly. A good reducing flame should be a long luminous cone, the end of which is faintly blue. The most effective part is between *a* and *d*, and the assay should be totally covered by this part (Fig. 3).

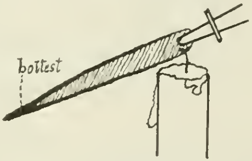

FIG. 2—OXIDIZING FLAME

In general it may be said that an oxidizing flame is used when some undesirable metal is to be slagged off and a reduction flame where it is necessary to collect metal.

As it is necessary to apply a flame steadily for quite a length of time, it is absolutely essential to know how to use the blowpipe correctly. For this purpose, rest the elbow on a table or board of convenient height, raise the forearm until vertical, grasp the stem of the blowpipe firmly with the four fingers, allowing the end nearest the mouthpiece to rest on the thumb, and press the pipe tightly to the lips. The blow should take place without stopping the natural breathing. Take a good breath of air and when the blowpipe is applied to the lips fill the space between the cheeks with air and blow. The cheeks act as bellows. When they are collapsed fill them again without stopping the breathing and continue the blowing. In this way only can a steady flame be applied for any length of time.

*Preparation of the Ore for Assaying.*—One of the most important operations is the correct sampling of the ore. Care must be taken to obtain an absolutely fair average sample of the material to be tested. It is best, of course, if the material has passed through a regular sampler, but as this is not apt to be possible for a prospector, it must be left to him to pick a fair sample.

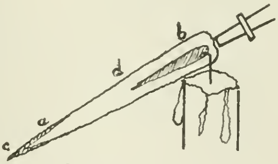

FIG. 3—REDUCING FLAME

A good scheme to follow is to take a representative sample of approximately 1 lb. of the ore, wrap it up in a cloth or several thicknesses of paper, and break it up as finely as possible with a prospecting hammer, on a flat rock, anvil or an iron plate. This done, spread the material out on a sheet of paper so that it forms a circle. With a stick divide this circle into four quadrants Fig. (4). This done, take the two diagonally placed ones (*A* and *D* or *B* and *C*) for further use and discard the rest (*BC* or *AD*). The material retained is again spread out in a circle, quartered and treated as above. Continue this operation until a sample of about 1 oz. is obtained.

This is then finely ground up in the steel mortar, and in the agate mortar until as fine as an ore used for ordinary assay work. At times a couple of sieves of small diameter (one 80-mesh and one 100-mesh) may prove useful. The sample thus obtained is put in a sample bottle and used for the assay.

*The Weighing Out of the Sample and the Fluxes.*—This, outside of the test lead, is done on the balance. Ordinarily 100 mg of sample are very carefully weighed out. If the ore is a very poor one, 200 mg may be used, and if very rich 50 mg. This, however, holds only for silver and gold ores. It is then necessary to make corrections.

For the weighing of the fluxes the accuracy need not be so great, but it pays to be saving in their use. For the test lead a separate device is employed. It consists of a cylindrical piece of wood having a graduation of 5, 10, 15, and 20 on it. These divisions represent 500 mg each, or in the language of the trade 5 Zentner. Over this wooden cylinder fits a glass tube of the same length as the wooden cylinder. All according to high the glass tube is raised one can, by filling the vacant part of the tube measure out 500, 1000, 1500, and 2000 mg of test lead. The weighing out may be done by using the point of a penknife.

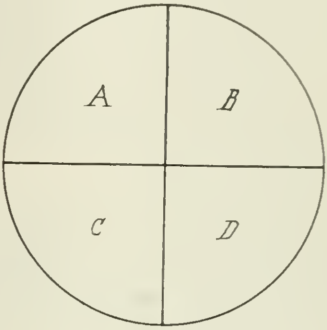

FIG. 4—QUARTERING

*Making Up the Charge and Wrapping in Soda Paper.*—The mixing of the ore and of the fluxes is done in the little horn scoop. The ore and fluxes are put in the scoop, care being taken that all of the weighed ore is removed from the scale pan. Then they are thoroughly mixed with the end of a penknife, and if required are ready to be put in the soda paper.

FIG. 5—TEST LEAD MEASURE

The procedure is as follows: One piece of soda paper is wrapped around the cylindrical wooden mold, allowing a piece of the paper to overlap the end of the cylinder. This end is then closed up, as you would wrap the bottom of a round flask, and firmly pressed against some flat, hard object so as to make it stay closed. The paper cylinder thus formed is carefully removed from the mold held lightly between the index finger and the thumb of the left hand, the closed end resting on the table or some flat object. The charge is then carefully taken from the scoop and put into this paper cylinder, care being taken not to spill any. The scoop is finally brushed down into the cylinder with a small camel's hair brush. With the platinum-tipped pliers the open end of the paper cylinder is then folded over several times tightly and finally the corners are turned up to prevent the small package from opening. Its appearance will be as shown in Fig. 6. This then is ready to put on the charcoal for reduction.

FIG. 6—CHARGE IN PAPER CYLINDER

Having discussed the main general features, we will deal with the special features in the next article.

# Coal Gas Residuals*

BY FRED. H. WAGNER

A hundred years of development have passed since Murdoch lighted the city of London with coal gas, and these years have placed gas lighting in the forefront of industrial progress, while the history of these years plainly shows how the proper utilization of by-products can revolutionize the magnitude of an industry. The early years of coal carbonization could depend upon no, or but very little, assistance from by-produce sales in the matter of cheapening the cost of production, and not until the aid of modern chemistry was called in, did the production of residuals make any appreciable change in this condition.

The recovery of residuals is a very important conservation of resources, and it forms one of the principal means of revenue to the coal gas producer, the sale of these residuals reducing the cost of gas production in a degree corresponding to the efficiency of the recovery methods adopted and the market value of the product.

The principal residuals recovered to-day are tar, naphthalene, cyanogen compounds, ammonia, and, in the case of coke oven gas, also benzol by a direct recovery method, and they will be treated in this consecutive order in the following pages; the recovery of benzol is confined almost entirely to the coke-oven plant, where a direct method of recovery is adopted, and to the tar distiller, benzol being one of the most valuable of tar constituents. While the recovery of naphthalene cannot exactly be termed one of profit in a pecuniary sense at present, the removal of a certain portion from the gas is of distinct advantage, and the methods adopted for its removal will, therefore, be given.

The gas produced during the carbonization of coal is a mixture of fixed gases, vapors of various kinds, and, at times, also globules of liquids, which are held in suspension, and are thus carried forward by the gas; these gases and vapors also carry forward some solid carbon in the shape of dust.

The principal fixed gases are hydrogen, $H_2$; methane, $CH_4$, also known as "marsh" gas; ethane, $C_2H_6$; propane, $C_3H_8$; butane, $C_4H_{10}$; ethylene, $C_2H_4$; small amounts of butylene, $C_4H_8$; propylene, $C_3H_6$; acetylene, $C_2H_2$; carbon dioxide, $CO_2$; carbon monoxide, CO; hydrogen sulphide, $H_2S$; nitrogen, N; oxygen, O, and ammonia, $NH_3$; while the principal vapors in the mixture are benzol, $C_6H_6$; toluol, $C_6H_5.CH_3$; xylol, $C_6H_4(CH_3)$ carbon disulphide, $CS_2$, and aqueous vapors. These latter vapors all pertain to substances which become liquid at ordinary temperatures, but the vapors of naphthalene, $C_{10}H_8$, phenols, etc., pertain to substances which become solid at ordinary temperatures, and must, therefore, be subjected to a special treatment.

As will be seen later, some of these constituents are of inestimable value to the coal-gas producer, and consequently the treatment of the gas after it is produced in the carbonizing plant, is of great importance; this treatment should not only consist of a method of cooling the gas, and thus condensing and precipitating the vapors as a fluid, but the method of treatment should be such as to retain in the gas those valuable illuminating constituents which may be lost to a greater or lesser extent in the usual condensing plant.

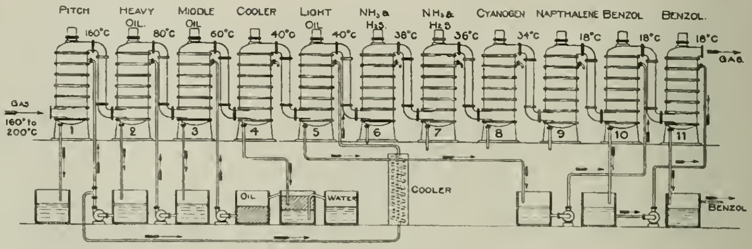

FIG. 1—FEED CONDENSING PLANT

The Feld system of condensation and purification of coal gas, which embraces successive cooling with a fractionation of the products, appears most attractive from the standpoint of efficiency and simplicity.

The usual condensing system in coal-gas practice embraces the use of a primary condenser, exhauster, tar extractor, secondary condenser, and ammonia washer; the tar, together with quite an ammount of illuminants, being thus removed in a greater measure by cooling, while in the Feld system, the gas is not cooled below a point where any volatile hydrocarbons are precipitated or absorbed by the effluent, the tar being fractionated in three washers into pitch, heavy oils, and middle or light oils, and the gas is treated for cyanogen compounds, combined hydrogen sulphide and ammonia, naphthalene, and finally benzol, the entire process being carried out in Feld vertical centrifugal washers, as shown in Fig. 1.

As will be seen from Fig. 1, the entire condensing plant consists of eleven washers, the first or pitch washer operating at a temperature of from 320 deg. to 392 deg. Fahr., the gas being kept at this temperature from the hydraulic main by insulating both the main and the pipe connections, or by the application of external heat, heavy oils from washer (2) being pumped into washer (1) where they are used as the active pitch extracting medium.

Washer (2) removes the heavy oils, and it is operated at a temperature of from 320 deg. to 176 deg. Fahr., all operating temperatures being determined from the actual dew-point of the gas for the constituent to be removed, the extracting medium being the middle oils from washer (3).

Washer (3) removes the middle oils, due to contact between the gas and the oils separated by cooling in washer (4), this cooling being effected by bringing the gas into intimate contact with water, the effluent from washer (4) being run into a separating tank where the oil is separated from the water by specific gravity.

The light oils are removed in washer (5) where the gases are washed by means of heavy oils which are previously cooled in a special cooler, these oils from (5) being run into a reservoir from whence they are pumped into the first benzol washer.

The washers for ammonia and hydrogen sulphide operate under a temperature of from 104 deg. to 97 deg. Fahr. the hydrogen sulphide being combined with the ammonia in these washers with the consequent formation of ammonium sulphate, while the cyanogen washer operates at about 97 deg. to 93 deg. Fahr.

The naphthalene is removed in washer (9) at a temperature of about 65 deg. Fahr., while washers (10) and (11) serve to extract the benzol and its homologues, the partially saturated oil coming from washer (10) being pumped into washer (11).

When this paper was contemplated, it was the desire of the author to treat each residual in a more exhaustive

---

*Paper read before the American Gas Institute. Copyright, 1914, by American Gas Institute. Subject to author's corrections.

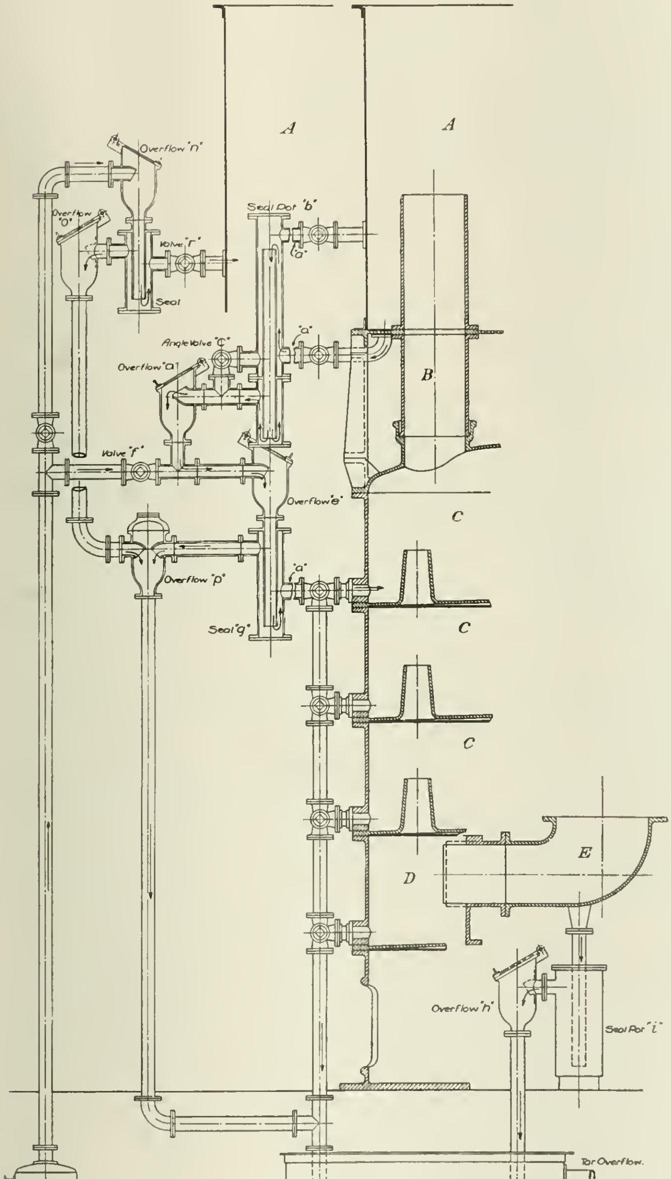

FIG. 2—FELD HOT TAR WASHER

manner, but owing to the large amount of data prepared the contents passed beyond the bounds of a paper of this character, and consequently it became possible to herewith present only the more essential features of residual recovery and the possible profits which might accrue due to the adoption of modern methods of operation.

### Tar

Tar is thick, dark brown, viscid, oily liquid, produced during the dry oscillation of coal; its chemical nature is very complex, and it contains a large number of compounds. The crude gas leaving the retorts is a mixture of permanent gases, but this mixture carries with it quite a number of hydrocarbons and other vapors, and as the illuminating, as well as the calorific, quality of coal gas is, in a great measure, dependent upon its hydrocarbon constituents, it is of prime importance to treat the gas so as to retain as many of these hydrocarbons as is possible. A reduction in temperature, however, soon reduces the hydrocarbons of greater density to liquid form, and this liquid is usually termed "tar." In spite of the fact that the gas temperature at the hydraulic main is perhaps never lower than 145 deg. Fahr., large quantities of tar are deposited at this point, and it is, therefore, almost impossible to retain the hydrocarbons of this class in the gas with the usual method of condensation.

Both the nature of the coal used and the temperature of carbonization exercise a great influence upon the quantity, as well as upon the quality of the tar produced, thus both quantity and quality regulating the amount of revenue received, and in this manner, governing, to a great extent, the final cost of gas production.

In the usual systems as applied at present, the removal, or the precipitation of tar, is accomplished by condensation or cooling; quite an amount of condensation occurs between the retort and the hydraulic main, a further amount of tar being deposited in the hydraulic main proper, after which the gas is conducted to the condensers where gradual cooling further reduces the tar content. After leaving the condensers, the gas still contains quite a number of tar globules in suspension, it being possible to remove only these last traces of tar by means of friction.

In the Feld system, a different method is employed as the heat contained in the gas is utilized by a system of fractional coolings to separate, or wash out of the gas, tar in several of its principal constituents. This treatment may also be varied in such manner as to prevent the formation of tar as much as possible by maintaining the heat of the gas coming from the retorts at a temperature above the dew-point of the gas for the constituents of high boiling points. This may be done by covering the connections from the retorts to the first washer with insulating material, or by applying heat to the exterior of the pipes. The gas thus protected is led to the washers where it is subjected to fractional cooling and successive washings at successively lower temperatures, so that the various tar constituents are separated from each other by employing the temperature of the gas itself, and without the necessity of employing extraneous heat after previous cooling.

A Feld washer especially arranged for hot tar washing is shown in Fig. 2 and in order that aqueous condensation may be avoided in the washer by reducing the temperature of the gas to the dew-point for water, the washing tar should be heated to from 40 deg. to 60 deg. Fahr. above the temperature of the gas at the inlet to the washer, this hot tar being the active tar extracting medium.

In Fig. 2, which shows a portion of a Feld washer with superimposed Pelouze condenser, *A* is a Pelouze condenser; *B*, gas port in washing chamber; *C*, upper washing chamber; *D*, lower washing chamber; *E*, gas inlet; *k*, basin, or tank containing wash tar; *r*, radiator, or steam coil; *l*, rotary tar pump; *m*, preheater for wash tar; *s*, insulated connection from tank (*k*) to pump (*l*).

In order to keep the wash tar at the desired temperature, the steam pipe from *m* is beneath pipe *s*.

The hot wash tar is pumped from tank *k* through the insulated connection *s* and preheater *m* to the Pelouze condenser *A* through the overflow pot *n;* any surplus tar overflows at *O* and *p* and returns to tank *k*.

The tar overflows from the Pelouze through *b* and *d*, *e* and *g*, into the upper chamber *C* of the washer, where it is picked up by the washing cones within the chamber and spread out over the entire gas space, the depth of the spray being from 8 in. to 14 in. depending upon the size of the washer. The gas is thus brought into intimate contact with the hot wash tar, and is subjected to a thorough washing, the wash tar as well as the tar expelled from the gas, overflowing through the gas port to the next lower washing chamber; here the wash tar is again placed in circulation by the cones in this chamber, and the total combined tar finally leaves the washer through the pot *i* attached to the gas inlet connection, and by means of overflow *h* enters tank *k*, all surplus tar from this tank flowing off to the tar storage.

In order that the maximum results may be secured, the wash tar should be constantly circulated through the washer, but it is not always necessary to circulate it through the Pelouze condenser, this omission being dependent upon the condition of the tar in the gas. The amount of hot tar to be circulated through the washer may vary from 0.5 to 2.5 gallons per 1000 cubic meters of gas per hour; larger volumes of gas require proportionally less circulating tar than do smaller volumes, but the amount of washing tar circulated must be so regulated as to prevent the temperature of the gas reducing the temperature of the wash tar.

The circulating wash tar should be pumped through the preheater *m* before it enters the washer, this preheater being supplied with a steam coil, and in some cases it may be necessary to insulate the tank containing the wash tar, depending upon its location, and even the washer proper with some insulating material, in order to increase the efficiency, as many of these washers are set up in the open in Europe, being thus exposed to the weather.

The tank containing the wash tar is also provided with a steam coil, or radiator, made in one piece in order to prevent leaks and thus mix water with the tar. Care must be exercised in operation to the extent of preventing the deposit of thick tar in the Pelouze condenser, and if the washer should be stopped for any reason, it must be emptied of tar at once in order to avoid cooling the tar and thus clogging up the passages.

Table I gives the results secured in washing with hot tar, the washer being supplied with a Pelouze condenser in the one instance, but not in the other.

TABLE I—FELD HOT TAR WASHING

Washer Without Pelouze Condenser

| Gas temperature at Inlet to Washer | Tar Content in Grains per Cu. Ft. | | Grains Removed | Efficiency, per Cent | Gas passed per 24 Hrs., Cubic Feet |
|---|---|---|---|---|---|
| | Inlet | Outlet | | | |
| 131° F. | 11.512 | 0.2930 | 11.219 | 97.46 | 2,463,000 |
| 127° F. | 10.386 | 0.2160 | 10.170 | 97.92 | 2,453,832 |
| 129° F. | 10,818 | 0.2930 | 10.525 | 97.29 | 2,341,800 |
| 129° F. | 13.518 | 0.4170 | 13.101 | 96.92 | 2,397,000 |
| 126° F. | 9.907 | 0.5250 | 9.382 | 94.70 | 2,400,000 |
| Washer With Pelouze Condenser | | | | | |
| 140° F. | 10.050 | 0.0436 | 10.0064 | 99.56 | 2,600,000 |
| 194° F. | 13.100 | 0.0872 | 13.0128 | 99.34 | 2,600,000 |

The Feld process of tar washing was installed in a works in Bohemia in 1907, and the tar was fractionated into pitch, heavy oil, and light oil, with the result that the tar produced by the old method of condensation sold for $5 per ton, while with the use of the Feld system producing the oils direct from the gas, the equivalent of this ton of tar sold for $16.

### Naphthalene

Naphthalene ($C_{10}H_8$) is a hydrocarbon and has a melting point of 174 deg. Fahr., a boiling point of 424 deg. Fahr., and it sublimes at lower temperatures. The deposition of naphthalene in a solid state in the mains or apparatus causes many operating difficulties, as it decreases the cross-sectional area of the gas conduits and thus produces quite some back pressure on the works.

The presence of naphthalene in the gas is probably due to the high heats employed in present-day carbonization, and it is presumed that these high heats cause a partial distillation of the tar with the consequent formation of naphthalene.

The greater portion of the naphthalene produced especially with high distillation or carbonization temperatures, goes over into the tar, the gas containing only a portion of the naphthalene vapor, its maximum content being dependent upon saturation at various temperatures, but outside of the temperature of carbonization the amount of naphthalene present in the gas is also due to the character of the coal used, and upon the time of contact between the gas and hot coke and hot retort walls.

The amount of naphthalene required to saturate a gas varies according to different investigators, none of them agreeing with each other.

In order to avoid stoppages in the pipe connections due to sublimation, it would be necessary to cool the gas as nearly as possible to a temperature corresponding to that of the gas in the buried mains, but as it is almost impossible to do this during cold weather, it becomes necessary to remove the naphthalene from the gas by means of a suitable extracting medium.

The best solvents for this purpose are anthracene oil, creosote oil, and water gas tar; the tar from vertical retorts has also been used for this purpose, but this tar must first be subjected to complete cooling.

If all of the naphthalene should be removed from the gas, the latter would suffer considerably in candlepower, and no more should be expelled than what would produce sublimation with consequent stoppages.

Under ordinary conditions, 100 grains of anthracite oil will absorb from 10 to 25 grains of naphthalene, according to temperature, but before using this oil from 3 to 4 per cent of benzol should be added, this addition leading to greater extraction efficiency, this efficiency being further increased by thoroughly and slowly cooling the gas, as the absorption is most complete at a temperature of from 60 deg. to 70 deg. Fahr.

One per cent of creosote oil will, under ordinary conditions, absorb one per cent of naphthalene, by weight, but this absorption is dependent upon the amount of phenols present.

Water gas tar will absorb from 18 to 20 per cent. of its own weight in naphthalene, this absorption efficiency also being dependent upon the amount of phenols present.

If water gas tar, or if water gas oil, is used as the absorbing medium, it can be run back to storage bearing its naphthalene burden, as the latter is not detrimental to the further use of the tar or oil, but if antracene or creosote oil is used this oil can be regenerated for further use by being distilled and condensed, the naphthalene crystals being thus caused to crystallize out.

An attempt has lately been made to use naphthalene as fuel in internal combustion engines, and some success has been met with in this direction; the present drawback seems to be the fact that it is necessary to start the engine with gas or some liquid fuel, and to so operate it until the heat generated by the engine is sufficient to melt the naphthalene, after which the latter is fed to the engine, vaporized, and exploded. Complete success in this direction would soon open up another source of revenue to the producer of coal gas.

It may be interesting to state that a locomotive operating on naphthalene has recently been constructed in France; this locomotive is provided with four cylinders, each two cast en-bloc, 5-5-in. bore by 8-in. stroke, 70 hp being developed at 950 r.p.m. This machine is provided with two carburetors, one used on starting with spirit, and the other for the naphthalene. The carburetor used in connection with the naphthalene is cast en-bloc with the reservoir in which the naphthalene is melted, double walls for the circulation of cooling water being provided, the temperature of this water being maintained at 212 deg. Fahr., thus maintaining a constant melting temperature.

### Cyanogen

Cyanogen ($C_2N_2$) is a gas composed of carbon and nitrogen, and it is probably produced during the period of carbonization in the form of hydrocyanic acid by the decomposition of some of the ammonia due to contact with the hot coke in the retort, as per the equation,

$$C + NH_3 = HCN + H_2,$$

and the amount of cyanogen produced by the carbonization of any particular coal bears a certain relation to the amount of nitrogen contained in the coal.

The removal of cyanogen from coal gas is of decided advantage for two reasons, (1) owing to its corrosive effect on works apparatus; (2) because it is a valuable by-product under certain conditions; also if cyanogen is permitted to pass on into the purifiers, it will be found to enter into combination with the iron in the purifying material, thus rendering a certain portion of this iron inactive for hydrogen sulphide extraction; on the other hand, the sale of spent oxide containing a high percentage of cyanogen is more remunerative than if it contained only sulphur, as this oxide is often purchased on the basis of its "prussian blue" contents only, "prussian blue" being the name applied to this cyanogen combination.

The revenue to be derived from the extraction of cyanogen from coal gas is dependent upon the amount of coal carbonized and upon the market price of the product, the latter fluctuating constantly; it is certainly not a remunerative proposition for works carbonizing less than 250 tons of coal per day, as the same labor expended on a plant of this size, can readily handle the proposition in one of double the capacity.

The estimated revenue in a plant carbonizing 250 tons of coal at the works, and 750 tons at another, the sludge from both being worked up in one plant, after deducting operating expenses and 6 per cent interest and 6 per cent for depreciation, amounts to $27,935 per year, and this, without the additional revenue, to be derived by the production of ammonium sulphate from the cyanogen press liquor, this liquor being sold on the basis of concentrated ammonia. Besides this revenue, the extraction of cyanogen in this case shows an aid of 22 per cent in the action of the purifiers, or the life of the oxide is increased by 22 per cent.

The two systems of cyanogen recovery which have met with the most pronounced success, is that of Bueb, and the one devised by Feld, the former making an insoluble ferro-cyanide coke, and the latter a soluble cyanide sludge.

For a description covering the extraction of cyanogen by the Bueb process, attention is called to the paper read by Mr. M. E. Mueller during the 1910 meeting of the Institute, and which appeared in the Proceedings of that year.

The Feld process of cyanogen extraction differs from that of Bueb in that it is applied after the ammonia has been removed from the gas, this alkali being replaced with milk of lime in the copperas washing medium. The combined solution of lime and copperas is run into the Feld vertical washer, the resultant sludge coming from the bottom of the washer being boiled and then filter-pressed, the product coming from the filter press being calcium ferro-cyanide.

The product coming from either the Bueb or Feld plant, is usually worked up into potassium ferrocyanide, and in this case the working up of the sludge produced by the Bueb system requires additional apparatus for the removal and concentration of the ammonia carried in the sludge, while the working up of Feld sludge obviates the necessity of this ammonia apparatus, as the Feld system embraces the removal of cyanogen from the gas after the ammonia has been extracted.

### Ammonia

Ammonia is a product derived from the destructive distillation of coal, and it results from the union of nitrogen with hydrogen, or $N + H_3 = NH_3$; besides being an important source of revenue, the removal of ammonia from gas is necessary on account of its destructive influence on the brass and copper work of meters and gas fittings; when burned with gas it gives off noxious fumes of oxides of nitrogen.

The usual method employed for the removal of ammonia depends upon its solubility in water, and at ordinary temperatures water can absorb about 708 times its volume of pure ammonia gas, the absorption increasing with a decrease in water temperature, or

| | | | | |
|---|---|---|---|---|
| One volume of water at | 32° F. | will absorb | 1050 | volumes of $NH_3$ |
| " | 50° F. | " | 813 | " " |
| " | 59° F. | " | 727 | " " |
| " | 68° F. | " | 654 | " " |
| " | 77° F. | " | 586 | " " |
| " | 183° F. | " | 180 | " " |

providing the pressure of the ammonia gas is equal to that of the atmosphere, and if the gas carries no tar burden.

The usual gas works method of operation. as practiced in America, removes the ammonia by condensation and washing, the first portion of the ammonia being removed in the hydraulic main due to the condensation of water vapors, which thus absorb ammonia. Cooling the gas in the condensers also causes the deposition of quite an amount of water which in turn absorbs more ammonia, the final ammonia being removed in the scrubbers or mechanical washers, using as little wash water as is consistent with the result desired, viz.: strong liquor.

Raw ammonia liquor from the plant usually contains from 1 to 2 per cent of ammonia, and due to the cost of transportation, it would not, in most cases, be economical to sell this liquor in its diluted state; the raw liquor is, therefore, usually worked up for one of the following ammonia products: (1) Concentrated liquor; (2) aqua ammonia; (3) sulphate of ammonia; but the product to be recommended for any particular gas works must necessarily depend upon local market conditions.

Concentrated ammonia is a product in which the raw liquor has been freed of a large portion of water, and it is used for producing other ammonia products.

Aqua ammonia is a solution of ammonia in distilled water, a great deal of it, in a dilute solution, being used for cleansing purposes.

Ammonium sulphate is produced by distilling the liquor, and absorbing in sulphuric acid; by passing the gas through an acid bath, thus absorbing the ammonia, or by combining the ammonia in the gas directly with the sulphur radical, discarding sulphuric acid.

The working up of the liquor is usually effected in continuous stills, Fig. 3, operating with a supply of live steam, and as the principle of design and operation is practically the same in the usual stills on the market, only one method will be described the other differing only in detail and not in principle.

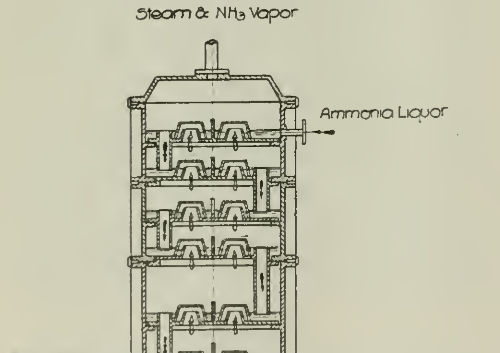

FIG. 3—AMMONIA STILL

The still usually consists of a series of superimposed sections, one mounted upon the other, constructed of cast iron, each section being provided with a steam passage in the bottom, covered with a hood or bell, and an internal overflow for liquor. These sections should be liberally provided with cleaning holes, by means of which access can be had to every part of the interior, so that the apparatus can be thoroughly cleaned without dismantling it. The liquor having been previously heated, enters at the top of the still and flows from section to section in a direction opposite to that of the steam, which enters at the bottom, passes up through the steam passages, and is caused to pass through the liquor by means of the hoods or bells.

The crude liquor is thus gradually brought to the boiling point, the free ammonia and other gases mixing with the steam in the upper portion of the apparatus. The milk of lime is introduced in small quantities into the lower or liming sections, the hoods of these sections having a somewhat deeper seal than the others, in order to permit of more efficient mixing of lime and liquor. A final boiling of the liquor in the lower sections completely liberates all of the fixed ammonia, and the stills should be so operated that the waste liquors leaving the bottom should not contain more than 0.005 per cent of ammonia.

If concentrated liquor is to be produced, the vapors coming from the still are washed in a lime washer in order to remove any carbonate of ammonia that may be formed, after which the vapors are condensed and run into storage.

The earning capacity of a concentrating plant operating in conjunction with a plant carbonizing 300 tons of coal per day, should be, with ammonia at eight cents per pound, about $25,788 per year, or

| | | |
|---|---|---|
| 375,000 lbs. of ammonia at 8 cents | | $30,000 |
| Labor | $1,830 | |
| Materials | 1,922 | |
| Miscellaneous | 460 | |
| Total operating cost, less interest and depreciation | | 4,212 |
| Profit per year | | $25,788 |

If the weak liquor, as produced in the works, can be sold as such, and if the ammonia in this liquor, based on the above prices of concentrate, is worth 6 cents a pound, the yearly gross revenue for this ammonia should be $22,500, but from this would have to be deducted the added freight due to shipping a larger bulk, if the ammonia liquor is to be transported away from the works, as well as pumping charges. In order to make the sale of weak liquor a profitable undertaking as compared with concentrate, it would be necessary that an ammonia works, which would take the entire output of liquor, be established in very close proximity to the gas works.

If aqua ammonia is to be produced, the vapors from the still are sent into lime washers, coolers, charcoal filters, oil washers, caustic soda washers, and finally into the absorbers.

The earning capacity of an aqua plant of the same size as that quoted above, should be about $47,030 per year, or

| | | |
|---|---|---|
| 780 tons of 26 Be' aqua at $102 | | $79,560 |
| Labor | $3,630 | |
| Materials | 7,610 | |
| Miscellaneous | 21,290 | |
| Total operating cost, less interest and depreciation | | 32,530 |
| Profit per year | | $47,030 |

If sulphate is to be made from the ammonia vapors, these vapors are sent into the saturators containing sulphuric acid, where the ammonia and the acid combine to form the sulphate, and the earning capacity of such a plant of the same size as those quoted above, should be about $30,809 per year, or

| | | |
|---|---|---|
| 727 tons of sulphate at $60 | | $43,620 |
| Labor | $1,830 | |
| Material | 10,221 | |
| Miscellaneous | 760 | |
| Total operating cost, less interest and depreciation | | 12,811 |
| Profit per year | | $30,809 |

The net earnings of these three plants is based on 250 maximum working days.

During the last fifteen years, the attention of investigators has been turned toward an endeavor to simplify the methods used to produce ammonium sulphate from the product due to coal distillation, and instead of treating the gas liquor itself, as in the old or indirect system just described, the endeavor has been to pass the gas directly into and through the saturator, which is a closed one in this case; this method of procedure has been termed the "direct process" and, as the name indicates, it is a reversal of the old method. Other investigators have proceeded along somewhat different lines, and while passing the gas through the closed saturator, they, at the same time, vaporize the ammonia produced by previous condensation and then pass these vapors into the saturator in conjunction with the gas, this latter development being known as the "semi-direct" process.

The Feld system is even more truly a "direct process" than any of the methods mentioned above, as saturators containing sulphuric acid are not used, and when it is remembered that the production of one ton of sulphate requires approximately one ton of acid, the importance of this advanced step can be realized, Feld combining the sulphur in the gas with the ammonia, thus producing ammonium sulphate by his polythionate process, no other oxydizing agent, except atmospheric oxygen being required, and the latter is used only in the sulphur stove where the sulphur is burned to form sulphur dioxide, this sulphur stove thus displacing the sulphuric acid factory which has hitherto been a necessity.

The method of operation can best be understood by following the diagram, Fig. 4. The plant is started by filling the two generator tanks *B* and *C* as well as the wash liquor tank *D* with weak ammonia liquor from the

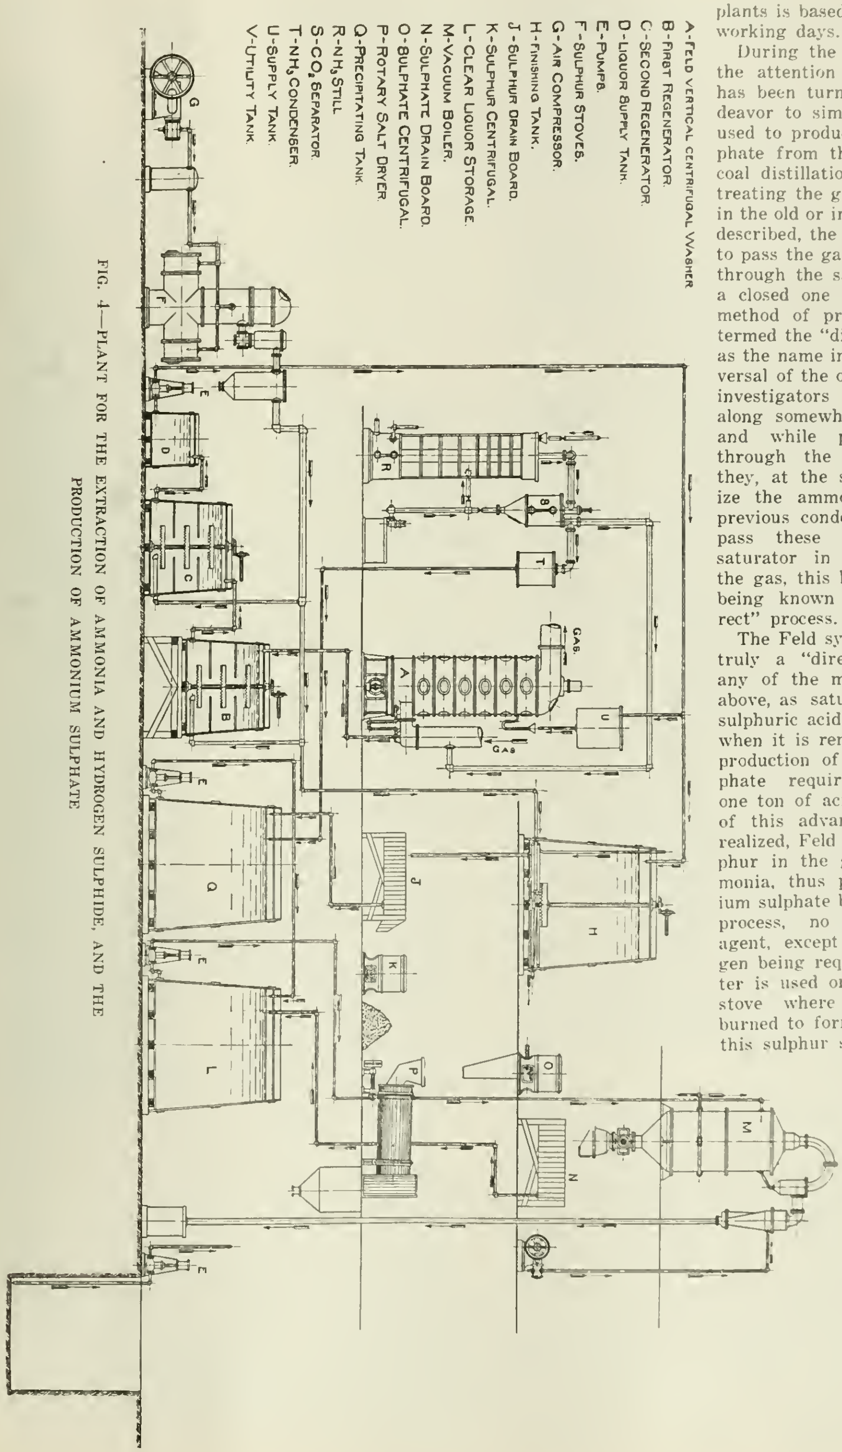

FIG. 4—PLANT FOR THE EXTRACTION OF AMMONIA AND HYDROGEN SULPHIDE, AND THE PRODUCTION OF AMMONIUM SULPHATE

works or with fresh water, this liquor or water being then pumped into the supply tank *U*, from whence it flows into the top of the washer *A*. Ammonia extraction immediately follows, and the liquor flows from the bottom of the washer as thio-sulphate, entering regenerator *B* where it is treated with sulphur dioxide coming from the sulphur stove *F*, the sulphur dioxide being forced through the liquor due to pressure produced by the compressor *G*. The overflow from regenerator *B* enters regenerator *C*, where a further treatment with sulphur dioxide is effected, and then enters the wash liquor tank *D*, from whence it is again pumped to the washer.

Alternately treating the liquor with sulphur dioxide and with crude gas forms polythionate in the first instance and thio-sulphate in the second, the polythionate being the active washing medium; an equivalent amount of hydrogen sulphide is removed from the gas in conjunction with the ammonia in the washer.

When the liquor has obtained a strength equivalent to 35 or 40 per cent ammonium sulphate, a portion of this concentrated solution is pumped into the oxidation or finishing tank *H*, it being replaced in the circulating system with weak liquor from prior condensation. In the finishing tank *H* the polythionate liquor is treated with heat through the medium of a steam coil, and some sulphur dioxide, if this should be necessary; by this treatment the thio-sulphates are transformed into polythionates which are in turn decomposed into sulphate and free sulphur.

The liquor, when decomposed, is drawn off from the finishing tank onto the sulphur drain board *J*, and the free sulphur, which is in the form of hard grains, is placed in the centrifugal *K* where its moisture is expelled; this sulphur is returned to the sulphur stove *F* for the forther production of sulphur dioxide.

The liquor from the drain board *J*, as well as that from the centrifugal *K*, flows to the precipitating tank *Q*, where it is treated with some concentrated ammonia, or $(NH_4)_2S$ from the condenser *T;* this liquor is then transferred to the storage tank *L* and is pumped from there to the vacuum boiler *M*. The concentrated ammonia, or $(NH_4)_2S$, from the still and condenser is sent into the precipitating tank in order that any iron held in suspension may be thrown down, thus ensuring a clean, white salt; the amount of ammonia used for this purpose is very small, but it is all recovered in the sulphate. The liquor is evaporated in a vacuum (an open evaporator may be used if desired) in the boiler, and the salts are drawn out onto the drain board *N* and from there to the centrifugal *O* and rotary dryer *P*, the salts thus produced being ready for bagging and shipping. All mother liquor from the drainboard and centrifugal returns to tank *L* and is from thence pumped back into the boiler.

The still *R* is used for the purpose of evaporating any ammonia liquor thrown down by previous condensation, these vapors being returned to the gas at the inlet to the washer, a small portion of the vapor being sent into the condenser *T* for producing the $(NH_4)_2S$ used in the precipitating tank. The use of a still is dependent upon the method of operation; if Feld's system of hot tar extraction is installed a still will not be necessary, as there will be no precipitation of ammonia under these conditions; a still is also not necessary if the production of ammonia liquor does not exceed the amount of liquor required in circulation.

This process requires but very little expert control, the usual mechanics, attending the machinery being capable of making the necessary liquor tests after some little instruction.

The Bueb process for the extraction of cyanogen produces ammonium sulphate in solution, and therefore, this process, in combination with the Feld explained above, forms a very remunerative proposition.

The income from such a combined plant in a works carbonizing 300 tons of coal per day is approximately as follows, based on 250 maximum days per year:

| | | | |
|---|---|---|---|
| Cyanogen | 128,500 lb. at 13.25c. | | $17,025.00 |
| Sulphate | 1,349,250 lb. at 3.00c. | | 40,477.50 |
| $NH_3$ in press cake | 29,750 lb. at 7.00c. | | 2,082.50 |
| Total gross earnings | | | $59,585.00 |
| The operating expenses are: | | | |
| Materials | | $3,695 | |
| Steam | | 1,663 | |
| Power | | 2,688 | |
| Miscellaneous | | 1,000 | |
| Labor | | 2,500 | |
| Total operating expense | | | 11,546.00 |
| Net earnings per year less interest and depreciation | | | $48,039.00 |

## Benzol

While the removal of benzol from gas is not of remunerative interest to the coal gas producer under the present antiquated standard of gas sale by candlepower, it is of special interest to the by-product coke oven operator, and as all of the preceding data applies to both of these producers, the method of removing and purifying benzol, is herewith included.

Benzol is recovered from coal gas after the tar and ammonia have been removed, and all modern systems are based on the original process as carried out by Brunck in Germany in 1887. The gas is washed in a series of washers with light oil, this oil absorbing the benzol, after which the raw product is subjected to a number of distillations, producing benzol, toluol, xylol and solvent naphtha.

The Koppers Company states that the income due to the extraction of benzol from the gas produced by the carbonization of 2000 net tons of dry coal per day, is as follows:

| YEARLY RECOVERY | |
|---|---|
| Benzel, 67 per cent | 978,000 gallons |
| Toluol, 16 per cent | 234,000 gallons |
| Xylol, 8 per cent | 117,000 gallons |
| Solvent naphtha, 9 per cent | 131,000 gallons |
| Total | 1,460,000 gallons |
| With a gross income of— | |
| 1,460,000 gallons at 15 cents | $219,000 |
| Crude naphthalene, 330 net tons at $5.00 | 1,650 |
| Regenerated acid of 40° Bé., 360 net tons at $6.00 | 2,160 |
| Total gross income | $222,810 |
| The operating expense per year being— | |
| Raw material, consisting of wash oil, sulphuric acid, caustic soda | $15,000 |
| Steam for distillation, air compressor, loading pumps, acid regeneration and cooling water | 15,000 |
| Electric power for water pumps, oil pumps, agitator, illumination | 6,200 |
| Wages for three distillers and two helpers | 5,000 |
| Overhead expenses, fire insurance, maintenance and depreciation, assuming the cost of the complete plant to be about $300,000 | 30,000 |
| Calorific loss of the gas | 13,000 |
| Total operating expense | $84,200 |

giving a net profit of $222,810 — $84,200 = $138,610, or 46 per cent on the investment capital, and making the cost of producing one gallon

$$\frac{\$84{,}200}{1{,}460{,}000} = 5.8 \text{ cents.}$$

This profit is, of course, dependent upon the selling price of benzol and the cost of raw material.

The Bartlett Hayward Company, Baltimore, Md.

**Recording Liquid Meter.**—The Duquesne Light Company, of Pittsburgh, Pa., will employ two 300,000-lb. per hour Lea V-notch recording liquid meters of the Yarnall-Waring Company, of Philadelphia, Pa., for the measurement of condensate in their Brunots Island power plant. The Duquesne Light Company having previously installed three meters of the same capacity, now uses therefore five Lea recording meters for measuring the flow of water at the rate of 1,500,000 lb. per hour.

# Niagara Falls Meeting of the American Electrochemical Society

The twenty-sixth general meeting of the American Electrochemical Society was held on October 1, 2 and 3 at Niagara Falls. It was very well attended and favored by ideal weather. The arrangements, made by the Niagara Falls members of the Society, under the leadership of President F. A. Lidbury, were excellent and the whole meeting was a most enjoyable affair in its social functions and thoroughly successful in its professional features; the most novel and brilliant of the latter being the symposium on experimental electric furnace work on Saturday.

The total registration was well above 200.

The following is a complete alphabetical list of those who registered at the meeting:

Paul O. Abbe, New York; W. L. Adams, Niagara Falls, N. Y.; Geo. P. Adamson, Easton, Pa.; E. H. Acton, Quebec, Canada; T. B. Allen, Niagara Falls, N. Y.; Mr. and Mrs. W. H. Arison, Niagara Falls, Ont.; T. F. Baily, Alliance, Ohio; A. N. Barron, Cleveland, Ohio; L. E. Barton, Niagara Falls, N. Y.; R. A. Bayard; E. H. Bedell, Chicago, Ill.; R. C. Benner, Freemont, Ohio; W. B. Bennett, Niagara Falls, N. Y.; Mr. and Mrs. W. F. Bleecker, Canonsburg, Pa.; Miss Elaine Bleecker, Canonsburg, Pa.; W. L. Bliss, Niagara Falls, N. Y.; E. Blough, Parnassus, Pa.; Dr. and Mrs. Wm. Brady, Chicago, Ill.; C. J. Brockbank, Niagara Falls, N. Y.; Geo. F. Brindley, New York; M. J. Brown, Niagara Falls, N. Y.; Mr. and Mrs. deCourcy Browne, New York City; A. R. Bullock; J. T. Burt-Gerrans, Toronto, Can.; Joe F. Callahan, Niagara Falls, N. Y.; C. F. Carrier, Jr., St. Louis, Mo.; A. W. Carroll, New York City; H. R. Carveth, Niagara Falls, N. Y.; H. C. Chapin, Cleveland, Ohio; L. W. Chubb, Pittsburgh, Pa.; W. R. Clymer, Cleveland, O.; H. B. Coho, New York; Edw. H. Cole, Niagara Falls, N. Y.; Miss Sarah Coleman, Jonesboro, Ind.; W. G. Collinson, Niagara Falls, N. Y.; V. G. Converse, Niagara Falls, N. Y.; F. T. Cope, Alliance, O.; W. M. Corse, Buffalo, N. Y.; Mr. and Mrs. Alfred H. Cowles, Sewaren, N. J.; Wm. A. Cowan, Brooklyn, N. Y.; G. E. Cox, Niagara Falls, N. Y.; John A. Crowley, Brooklyn, N. Y.; J. S. Crider, Cleveland, O.; R. A. Crider, Cleveland, O.; T. E. Crossman, New York City; N. Cunningham, Timmins, Ont.; Thos. L. Cunningham, Niagara Falls, N. Y.; H. M. Cushing; C. Dantsizen, Schenectady, N. Y.; E. R. Dewart, Niagara Falls, Ont.; Bradley Dewey, Pittsburgh, Pa.; Jos. Dixon, Sheffield, Eng.; H. M. Doerschuk, Niagara Falls, N. Y.; J. V. N. Dorr, New York; H. L. Doyle, Niagara Falls, Ont.; C. L. Dunham, Niagara Falls, N. Y.; R. W. Earle, New York City; I. R. Edmands, Niagara Falls, N. Y.; John C. Egnia, Niagara Falls, N. Y.; R. M. Emblidge, Buffalo, N. Y.; L. S. Finch, Niagara Falls, N. Y.; E. C. Fish, Niagara Falls, N. Y.; Mr. and Mrs. F. A. J. Fitzgerald, Niagara Falls, N. Y.; R. E. Fowler, Niagara Falls, N. Y.; F. C. Frary, Minneapolis, Minn.; Mrs. P. M. French, Rochester, N. Y.; W. M. Frickes, Niagara Falls, N. Y.; Mrs. W. M. Frickes, Niagara Falls, N. Y.; A. O. Fuller, Niagara Falls, N. Y.; G. Furness, Niagara Falls, N. Y.; Miss V. M. Gallinger, Niagara Falls, N. Y.; R. E. Gegenheimer, A. E. Gibbs, Plainpoint, Pa.; J. T. Gibbons, Bauxite, Arkansas; I. K. Giles, Niagara Falls, N. Y.; H. W. Gillett, Ithaca, N. Y.; Mr. and Mrs. B. L. Glascock, Niagara Falls, N. Y.; J. B. Glaze, Niagara Falls, N. Y.; C. M. Graves, Niagara Falls, N. Y.; J. R. Griffith, Niagara Falls, N. Y.; J. J. Geraty, Philadelphia, Pa.; Donald S. Hake, Niagara Falls, N. Y.; H. M. Hall, Maasena, N. Y.; C. G. Hardie, Buffalo, N. Y.; G. A. Hendrie, Niagara Falls, Ont.; Carl Hering, Philadelphia, Pa.; Alfred Herz, G. K. Herzog, Massena, N. Y.; F. N. Hicks, Niagara Falls, N. Y.; A. T. Hinckley, Niagara Falls, N. Y.; E. C. Hoffman, Niagara Falls, N. Y.; J. A. Holladay, Niagara Falls, N. Y.; L. S. Holstein, A. H. Hooker, Niagara Falls, N. Y.; H. W. Hooker, Niagara Falls, N. Y.; W. S. Horry, Niagara Falls, N. Y.; Mr. and Mrs. L. E. Howard, Lockport, N. Y.; W. F. Hubley, Newark, N. J.; O. Hutchins, Niagara Falls, N. Y.; D. A. Johnson, Chicago, Ill.; L. E. Imlay, Niagara Falls, N. Y.; J. A. Johnson, Niagara Falls, N. Y.; A. J. Jones, Niagara Falls, N. Y.; W. McA. Johnson, Hartford, Conn.; H. T. Kalmus, Kingston, Ont., Canada; Wm. Kastner, Buffalo, N. Y.; Mr. and Mrs. H. W. Kellogg, Niagara Falls, N. Y.; J. Kelleher, Toronto, Ont.; Mr. and Mrs. Frank R. Kemmer, Niagara Falls, N. Y.; F. L. Koethen, Niagara Falls, N. Y.; H. W. Lacey, N. Tonawanda, N. Y.; W. Laib; W. E. Lambert, Niagara Falls, N. Y.; P. E. Landolt, New York; A. M. Lawson, Niagara Falls, N. Y.; C. E. Leffel, Mr. and Mrs. F. A. Lidbury, Niagara Falls, N. Y.; M. G. Lloyd, Chicago, Ill.; Fred J. Longley, Niagara Falls, N. Y.; D. A. Lyon, Pittsburgh, Pa.; G. A. B. Lyster, Niagara Falls, N. Y., James H. Macbeth, Niagara Falls, N. Y.; J. H. MacMahon, Niagara Falls, N. Y.; J. R. MacMillan, Niagara Falls, N. Y.; Chas. G. Maier, Niagara Falls, N. Y.; W. Judson Marsh, Niagara Falls, N. Y.; J. G. Marshall, Niagara Falls, N. Y.; H. C. Martin, Niagara Falls, N. Y.; E. J. K. Mason, New York, N. Y.; F. C. Mathers, Bloomington, Ind.; M. E. McDonnell, Altoona, Pa.; Max Mauran, Niagara Falls, N. Y.; W. A. McKnight, Niagara Falls, N. Y.; J. D. McMahon, Niagara Falls, N. Y.; Mr. and Mrs. Ralph McNeill, New York; J. A. McSweeny, Niagara Falls, N. Y.; C. E. K. Mees, Rochester, N. Y.; W. G. Merriman, Lockport, N. Y.; D. R. Miller, Niagara Falls, N. Y.; John A. Miller, Buffalo, N. Y.; W. L. Miller, Toronto, Ont., Canada; J. B. Morden, Niagara Falls, N. Y.; Wm. C. Moore; Mr. and Mrs. W. R. Mott, Cleveland, O.; G. C. Moyer, Niagara Falls, N. Y.; J. M. Muir, New York; John H. Nee, Niagara Falls, N. Y.; J. G. Nelson, Niagara Falls, N. Y.; A. Neubeck, Buffalo, N. Y.; Fredk. G. Newell, Niagara Falls, N. Y.; J. D. Oille, Niagara Falls, N. Y.; J. L. Osborne, Niagara Falls, N. Y.; C. R. Pafenbach, Lockport, N. Y.; C. L. Parsons, Washington, D. C.; T. A. Patterson, Niagara Falls, N. Y.; L. A. Pettebone, Niagara Falls, N. Y.; N. Petinot, Niagara Falls, N. Y.; A. G. Porter, Niagara Falls, N. Y.; Mrs. A. G. Porter, Niagara Falls, N. Y.; A. F. Prenster, Niagara Falls, N. Y.; J. W. H. Randall, East Jordan, Mich.; Geo. R. Rayner, Niagara Falls, N. Y.; Jos. W. Richards, South Bethlehem, Pa., E. F. Roeber, New York; Miss Marie H. Rose, Niagara Falls, N. Y.; W. Ross, Niagara Falls, N. Y.; A. J. Rossi, New York; Prof. & Mrs. G. A. Roush, South Bethlehem, Pa.; J. M. Rowland, Niagara Falls, N. Y., D. A. Russell, Youngstown, Ohio; S. S. Sadtler, Philadelphia, Pa.; Mr. and Mrs. L. E. Saunders, Niagara Falls, N. Y.; E. S. Schartzer, Niagara, Falls, N. Y.; H. C. Schlatter, Niagara Falls, N. Y., C. G. Schluederberg, Pittsburgh, Pa.; S. R. Scholes, Pittsburgh, Pa.; C. M. E. Schroeder, Rutherford, N. J.; Mrs. S. R. Skinner, Denver, Colo.; Mr. and Mrs. A. W. Smith, Cleveland, Ohio, W. A. Smith, Niagara Falls, N. Y.; Walter F. Smith, Philadelphia; W. O. Snelling, Pittsburgh, Pa.; Mr. and Mrs. R. C. Snowdon, Niagara Falls, N. Y.; E. C. Speiden, Niagara Falls, N. Y.; E. C. Sprague, Niagara Falls, N. Y.; S. G. Stafford, Coraopolis, Pa.; F. A. Stamps, Niagara Falls, N. Y.; Aug. F. Stilleson, Niagara Falls, N. Y.; G. D. Stilson, Niagara Falls, N. Y.; C. E. Taylor, Niagara Falls, N. Y.; A. Thompson, Buffalo, N. Y.; C. B. Thwing, Philadelphia, Pa.; Mr. and Mrs. M. Toch, New York City; Mr. and Mrs. F. J. Tone, Niagara Falls, N. Y., C. P. Townsend, Washington, D. C.; C. A. Tryoa, Niagara Falls, N. Y.; R. Turnbull, Welland, Ont., Canada; F. M. Turner, Jr., Pittsburgh, Pa.; F. O. Tyler, Niagara Falls, N. Y.; L. D. Vorce, Wyandotte, Mich.; Wm. H. Walker, Boston, Mass.; Mr. and Mrs. Walter Wallace, Niagara Falls, N. Y.; Fred B. Wheeler, Chicago, Ill.; Mr. and Mrs. R. H. White, Niagara Falls, N. Y.; E. H. Whitlock, Cleveland, Ohio; W. R. Whitney, Schenectady, N. Y.; A. M. Williamson, Niagara Falls, N. Y.; R. S. Wilo, Pittsburgh, Pa.; Mr. and Mrs. J. R. Wilson, Niagara Falls, N. Y.; N. A. Wilson, Niagara Falls, N. Y.; C. A. Winder; Mr. and Mrs. Chas. Wirt, Germantown, Pa.; J. A. Yunck, South Orange, N. J.

The first two meetings for the presentation and discussion of papers were held on Thursday morning and Friday afternoon at the Clifton Hotel, the third professional session, devoted to the symposium, at the FitzGerald Laboratories. Abstracts of all the papers and discussions are given below.

### Social Functions

On Friday evening a banquet was held at the Clifton Hotel. As a novel feature there were no after-dinner speeches, but instead a very elaborate illustrated lecture by Dr. C. E. Kenneth Mees, director of the research laboratory of the Eastman Kodak Company, on "the physical nature of color." The experimental demonstrations were charming.

Very enjoyable, too, was the excursion to Foster's Flats, on the afternoon of Thursday. This is a delightful spot near the Whirlpool Rapids, and the party enjoyed the presence of a local authority on the flora, fauna and history of the locality. The announcement in the program to the effect that "undoubtedly arrowheads can be found in large quantities in the vicinity" was made good, some one hundred or two having been specially cast for the occasion. The trick was discovered when some arrow-heads of Acheson graphite were found.

### Excursion

The morning of Friday was devoted to an excursion to manufacturing plants.

The Acheson Graphite Company's works were first visited, where the making and pressing of large amorphous carbon electrodes and their subsequent transformation into graphite in electric furnaces were found exceedingly interesting.

The plant of the Niagara Alkali Company, much enlarged in recent years, was next visited. It is interesting in more than one respect. It is the only American plant in which potassium chloride is electrolyzed, the Billiter-Siemens & Halske horizontal-diaphragm cell being used. The output of caustic potash is chiefly sold for special soaps, but also for electroplaters' supplies, etc. The chlorine is partly worked up into bleaching powder, partly liquefied and sold as liquid chlorine, and partly worked up into hydrochloric acid (by com-

PHOTOGRAPH TAKEN BEFORE THE CLIFTON HOTEL AT THE

bination with hydrogen which is evolved at the cathode).

After this the party divided. One half visited the triple-plating department of the Spirella Corset Company, the other half the power plant of the Cliff Electrical Distributing Company (the old Schoellkopf plant).

### The Smoker

The smoker, a very big feature of the entertainment program, was held on the evening of Thursday at the Clifton Hotel. There were large, round, red and white badges with the inscription "Safety Last—Niagara Falls, the Home of Section Q." Mr. L. E. Saunders, president of Section Q, was in charge of the smoker and was very effective.

There was a long, continuous performance without an idle moment. Mr. J. Macbeth discussed the personnel of the local electrochemical industry of Niagara Falls from the point of view of a street sweeper who hears many things that other people don't hear.

Mr. F. A. Lidbury lectured on what was an alleged continuation of Dr. Bancroft's work on electrolytic flames, showing the phosphoresence produced by the solution of effervescent cathartics, the deposition on cooled porcelain tubes of metals from the steam of boiling solutions of those metals and other instances of "those remarkable phenomena which had completely escaped Dr. Bancroft's notice." The lecturer explained that as Dr. Bancroft had cast aspersion in his lecture on his (the lecturer's) knowledge of his own business, a "tu quoque" became necessary.

MAZDA LISA
A CARTOON FROM THE SMOKER

Mr. Max Mauran whistled and there was a sketch giving a life-like presentation of the proceedings of a factory inspection, conducted by a State factory investigation committee, entitled: "Show the ladies what you got."

The parts of the ladies were charmingly assumed by Messrs. D. Stubblefield and J. Glaze, while Mr. M. Bartlett presented with authority and Mr. P. McN. Bennie with forcefulness and Scotch accent the parts of Haskell-Jones and Angus-McBullgang, respectively manager and foreman of the Potash Carbide Abrasion Company of America. Messrs. R. Wilson, A. H. Hooker and A. T. Hinckley carried very naturally the parts of the workmen.

Slides, passed by the Censor—more or less personal, but all of them very amusing—illustrated the reports made by the different committees of Section Q. As an example we reproduce the Mazda Lisa cartoon from part II of the committee on advertising.

Then there were five entirely new songs, as well as all the old favorites of Section Q. They were not passed by the Censor. Hence we are only able to print one and a portion of another.

This is the song about Johnny, the plater:

"Johnny took some acetate, Johnny took some lead, Johnny took some poplar bark and stood it on its head, John added HCl until the bath was clear, But Johnny never knew why it plated out so queer.

"Johnny took some copper salt, dissolved in cyanide, And added dextrine, glue and snuff and aloes on the side, He spat in some tobacco juice and then he added beer, But Johnny never knew why it plated out so queer.

"Johnny used up fifteen volts for every gross of forks, Just as recommended in the platers' helpful talks, And other confidential hints were whispered in his ear, But Johnny never knew why it plated out so queer.

"O! Up came Banny with a supercilious air, And told him he'd been going wrong, and when and how and where, And Bennett wrote long papers then to make the matter clear, And now Johnny knows why it plated out so queer."

A portion of another song ran as follows:

"The furnace has a jolly time, Reducing tons of coke and lime, But when a carbon breaks, I guess, It makes an awful, awful mess.

"How useful is the humble cell, In breaking up NaCl, But when the diaphragm goes wrong, The Superintendent's face grows long.

"The Static is a patient beast, Abused the most and grumbles least, But when it does go on the bust, It gets most competently cussed.

"The load-peak meter is a pest, Its accuracy is a jest, It prints a great continuous lie, And when the bills come in they're high.

"The power house has an easy life, So free from troubles and from strife, It cooks up surges on its bus And sends them straight away to us.

"The abrasive's life is very hard, It grinds up metal by the yard, and carborundum is the one, The other's christened crystolon."

The smoker came to an untimely end at 11 o'clock through the heartless operation of the stringent Ontario liquor law.

NIAGARA FALLS MEETING OF THE AMERICAN ELECTROCHEMICAL SOCIETY

### Base-Metal Thermocouples

President Lidbury called the first professional session to order on Thursday morning.

A paper by Professor O. L. KOWALKE, of the University of Wisconsin, discussed the constancy of base-metal thermocouples as related to the microstructure.

Five different samples of thermocouples wires were investigated and the results are given in detail in the paper. The original structure as well as the structures produced by a two-hour heat treatment at 400 deg., 600 deg., 800 deg. and 1000 deg., respectively, were studied. From the results it appears that those metals which form solid solutions with one another, give the best results, providing that the thermo-electric force is satisfactory and the melting point high.

The characteristics of solid solutions were found for the following alloys: nickel-iron, low in iron; nickel-chrome; chromium-iron-nickel; aluminium-nickel; nickel-copper; constanton; excello.

Silicon does not appear to be a desirable constituent in a nickel alloy for thermocouple material.

Any segregation of the metal has an undesirable effect on the constancy of the couple. Wires containing but one metal showed a satisfactory structure.

The paper elicited an extended discussion.

Mr. W. R. Mott referred to the fact that freshly made alloys frequently change their structure and crystallize out after having been taken from the furnace. Silicon is peculiar in another way in its thermo-electric characteristics, since deoxidized pure silicon behaves differently from silicon containing dissolved silica.

Mr. C. B. Thwing, in a written communication, said that in a former investigation of the relation between thermo-electromotive force and coefficient of expansion he met some striking exhibitions of the effect of aggregation of crystals as changed by heat upon both of these properties of certain alloys and metals, for instance, antimony. He suggested that Professor Kowalke apply the same tests to platinum thermocouples. Such couples when damaged by long use may often be restored by glowing them with a current not sufficient to melt the wire, but to reach, say, 1500 degrees. Microphotographs of the structure before and after the heating would be of great interest.

Prof. Jos. W. Richards said it was a fact that so-called standard couples which had been standardized and probably accurately standardized in the laboratory of the maker, when brought to the works and used there, sometimes show variations of from 10 to 100 degrees C. from the standardization. Mr. B. L. Glascock referred to a recent case in which four couples, supposed to have been standardized by the manufacturer, when checked against a platinum, platinum-rhodium couple, varied from 8 to 52 degrees at 1000 deg. temperature. Mr. W. McKnight added that the couple, of secret composition, is manufactured for use at 1200 deg.

### Electrometric Titration

A paper on this subject, by Mr. HENRY ZIEGEL, of Brookline, Mass., concerns a possible technical application of the change in potential at the end point when a bichromate solution is reduced by a solution of ferrous salt.

The change in potential in a solution at the end point of a titration has been studied by several workers during the last fifteen years. Recently Hildebrand and especially Forbes and Bartlett, have studied this change in potential in the ferrous iron-bichromate titration. Under the conditions observed by the latter authors, this potential change is about 0.2 volt and even greater. The present author has been successful in applying this change in potential to the regulation of the burette stopcock in such a manner that the stopcock closes automatically when the end point of the titration is reached.

The apparatus used is similar to that of Forbes and Bartlett, with the following changes: In place of the usual galvanometer, a Weston No. 30 relay was used. Thus when the change in potential took place, immediate contact was made in a circuit having in it a telegraph sounder with a narrowed arm seven inches in length from fulcrum to tip. This sounder arm tip was connected to one side of the burette stopcock by means of a piece of fine chain. Final connection was made to the stopcock tip by a small brass cap cemented on with sealing wax. Such a device closed the stopcock, and a similar sounder was adjusted to the other extremity of the stopcock so that the latter would be opened by it.

Thus, at the initial potential in the solution to be titrated, the arm of the Weston instrument completed a circuit which opened the burette stopcock, and at the end point the change in potential caused the needle to swing a few hundredths of an inch, open the above circuit, and close the circuit containing the sounder which caused the stopcock to close. That is, the change in potential at the end point can be caused to close the burette stopcock mechanically, thus showing the first step in the accomplishment of titrations by other than manual operations.

The rapid stirring necessary was accomplished by using the elongated shaft of a cheap battery motor. This shaft was heavily platinum plated, and tipped with a deeply nicked disc of sheet platinum. This platinum formed the oxygen electrode. An ordinary form of calomel electrode was used. The galvanometer used was a rewound stock Weston No. 30 relay.

The procedure was to set the beaker containing the bichromate in place, close the stirring motor circuit, and then close the switch controlling the two sounders. The burette would then deliver until the end point was reached, when, due to the potential change, the stopcock would be closed by the second sounder. These two sounders were actuated by the delicate Weston instrument.

The author proposes to apply this apparatus to the automatic titration of iron after the direct procedure of Hildebrand and to the titration of zinc by ferrocyanide.

In the extended discussions which followed, Prof. G. A. Roush, referred to similar published work of two other authors though the titration had not been rendered automatic by them. He thought that by the use of such automatic methods, the time for routine analytical work, for instances, in iron and steel laboratories, could be largely reduced.

Mr. Warren F. Bleecker, on the other hand, thought such methods were academic and referred to a similar method he had employed in permanganate titration using a ray of light and its effect on a selenium cell.

President Lidbury thought there were cases where electrometric titration would have considerable advantages over ordinary methods. For instance, in determining very small amounts of chlorides in water, a silver electrode as an indicator gives an accurate sharp end point. The method is very sensitive. Another application is the determination of the acidity or alkalinity of solutions containing hypochlorites.

Dr. W. R. Whitney said that if we add the measurement of electrical resistance to this scheme of measuring electrometric forces, we have quite a group of possible electrical titrations. The resistance method is, for instance, useful for determining the neutral point in acid and alkali titration.

Dr. W. Lash Miller pointed out the accuracy of the author's method. In fourteen analyses made by the author's machine the number of cubic centimeters added automatically varied between 19.50 and 19.79, while in six spot plate checks, done manually, the variation was between 19.50 and 20.39.

Prof. Francis C. Frary thought that according to the author's figures the automatic results were 0.8 c.c. less than the manual results. Prof. Roush replied that the machine can be set to shut off the titration at any desired voltage so that one can adjust the operation to check exactly with his own titration.

Prof. Richards said that the time saved by the machine in titrations in large laboratories was not negligible.

President Lidbury suggested that the author's apparatus might be used as a simple control of certain large-scale industrial operations, for instance, in cases in which it is necessary to keep the solution neither acid nor alkali, but absolutely neutral.

Mr. Bleecker agreed that the method is accurate and that it is perfectly feasible to use it, but in practice there exists a prejudice against a complicated electrical device in a laboratory where one cannot afford expert attention.

Dr. William Brady thought that while electrometric titrations might be a good thing, they were not particularly applicable in iron and steel laboratories.

Mr. G. K. Herzog suggested the use of electrometric titration of chlorides in the determination of the flow of water by the titration method in hydraulic plants.

### Reproducibility of the Copper Electrode

In a paper by Professor Frederick H. Getman, of Bryn Mawr College, attention is called to the fact that in investigations of the e. m. f. of various concentration cells there is a frequent variation of the difference of potential between the common metals and solutions of their salts.

While the phenomenon appears to be quite general, in no case has it been more difficult to secure satisfactory reproducibility than with copper electrodes. A study of the reproducibility of the copper electrode was therefore undertaken. The chief results are as follows:

Of the various forms of copper electrode which have been studied, that in which spongy copper is employed is the only form which is constant and reproducible.

The irregularities observed with electrodes of massive copper and with electrodes of platinum covered with an adherent deposit of copper, may be ascribed to conditions of metastability. The spongy modification of the metal is to be regarded as the stable modification under ordinary laboratory conditions.

The spongy copper electrodes were fine platinum loops covered with a deposit of spongy copper obtained by electrolyzing a neutral solution of copper sulphate at high current density.

The paper was discussed by Messrs. W. C. Moore, G. A. Roush, W. R. Mott, J. W. Richards, Francis C. Frary, W. Lash Miller, and H. C. Chapin. The condition of the surface determines the e. m. f. and it is, of course, affected by mechanical or other treatment. Mechanical treatment causes strains in the metal and these have some connection with corrosion. The possibility of impurities (for instance, sulphides and hydrogen) in the copper deposit was also commented upon.

### Impurities in Cathode Copper

The sources of impurities in cathode copper were discussed in a paper by Mr. Lawrence Addicks, of Douglas, Arizona.

Several years ago, the author collected a large quantity of data in the endeavor to ascertain what rôle electrolyte included within the pores of the cathode body played in contamination, and many figures from the Raritan, A. S. & R., Balbach, Great Falls and Buffalo refineries were added to those available at the Chrome plant, with which he was especially concerned. The study proved to be too complex to yield conclusive results, but a number of relations were established.

Impurities in refined copper may (a) cause a low electrical conductivity; (b) result in brittleness or weakness; or (c) be a source of loss of by-products of value. The first class is represented by phosphorus, aluminium, silicon, arsenic and antimony; the second by bismuth, lead, tellurium, and selenium; and the last by silver, gold, platinum, and palladium. It is further interesting to note that class (a) forms with copper alloys of excellent mechanical properties, while class (b) is practically insoluble in copper, forming a brittle matrix around the copper grains in the cast bar.

From the refining point of view impurities may be due to (d) electrolytic deposition; (e) inclusion of electrolyte in the crystalline structure of the cathode; (f) mechanical contamination from anode slimes suspended in the electrolyte and attaching themselves to the cathode; and (g) substances entering during melting from furnace, fuel and tools, and from other outside sources. It must be remembered that the finished copper is guaranteed to run at least 99.88 per cent Cu, that it commonly does run 99.93 per cent in the melted bar and that it is very unusual to find 0.01 per cent of any one impurity except oxygen, probably as cuprous oxids in solid solution, or possibly some other dissolved gas, such as argon or carbon monoxide.

After a general discussion of the possible sources of each impurity, the author first takes up a detailed discussion of gold and silver.

Here abundant information is available, as the metal losses are always very closely watched. A very puzzling case developed, in that at two refineries the proportionate silver losses ran about twice the gold. A careful investigation brought out the fact that at one of them and probably at the other, the assay method used gave low results for gold on account of the very small quantity present and correcting this would doubtless bring the gold up to the silver figures. As the silver and gold in the anodes all go into the slimes, the cathode losses should be directly proportioned to the anode contents, assuming an equal amount of float slimes in the different refineries. With high current densities there is more disturbance in the tank, due partly to increased circulation than when low density is used. We should therefore expect increased percentage losses at plants where high current densities are obtained.

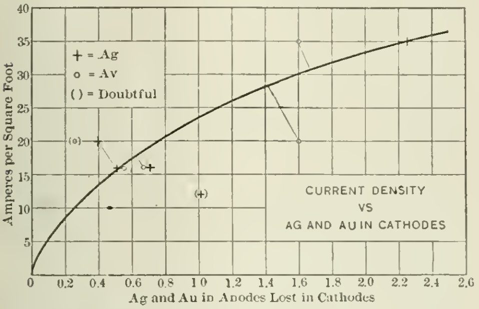

FIG. 1—CURRENT DENSITY VERSUS SILVER AND GOLD IN CATHODES

An inspection of Fig. 1 shows that current density has directly or indirectly a marked effect on the amount of slimes reaching the cathodes. Also that for densities between 15 and 20 amperes per sq. ft. (172-215 amp, per sq. m.), comprising most of the plants (the data in this paper are all from multiple-system plants; series plants are complicated by fouling of cathodes from adhering anode scrap) some 0.7 per cent of the silver and gold in the anodes adheres as slime to the cathodes, or in other words, the efficiency of refining is about 99.3 per cent. As the silver and gold in the anodes all goes into the slimes, this is the same thing as saying an equivalent amount of the anode slimes is carried over to the cathodes and knowing the analysis of the slimes, we should be able to figure the degree of fouling from this source. It will be of interest to test an actual case as in Table I.

TABLE I.

| Element | Per cent in Slimes | Per cent in Cathodes | Per cent Slimes X 0.000154 | Remainder | Per cent Fouling by Slimes |
|---|---|---|---|---|---|
| Ag | 33.82 | 0.00520 | 0.00520 | 0 | 100 |
| Te | 2.74 | 0.00023 | 0.00042 | Negative | 100 |
| As | 2.77 | 0.00105 | 0.00043 | 0.00062 | 41 |
| Sb | 5.40 | 0.00255 | 0.00083 | 0.00172 | 32 |
| Fe | 0.19 | 0.00330 | 0.00003 | 0.00327 | 1 |
| Ni | 4.98 | 0.00520 | 0.00077 | 0.00443 | 15 |
| Pb | 1.86 | 0.00070 | 0.00029 | 0.00041 | 41 |
| S | 2.01 | 0.00076 | 0.00031 | 0.00045 | 41 |

The case taken is one where the fouling as shown by the silver is twice normal, which, however, is of no harm as an example. Figures happen to be available for this period (which covers many million pounds of cathodes) for raw slimes, that is slimes that have simply been boiled free of soluble sulphates before sampling, whereas slimes are nearly always roasted and boiled in dilute sulphuric acid until practically copper-free before samples are taken and this operation somewhat disturbs the balance of impurities. The figures show clearly that except in the case of the insoluble group of elements before mentioned the slimes are not the only source of fouling. Except for iron and sulphur, the melting operation may slightly reduce impurities, but cannot increase them, so our argument is on the safe side.

The position can be attacked, however, on the ground that silver and gold are heavy and sink readily to the bottom of the tank, while the lighter oxidized impurities chiefly make up the float slimes. Emrich, in his paper on the "Refining of Blister Copper," presented before the American Institute of Mining Engineers, in 1904, argues backwards from the cathode analysis to prove this point and concludes that practically all the fouling comes from float slimes. Mr. Addicks thinks that some of the data submitted later show that his position is not sound. It is true that material collected at some distance away in launders, etc., runs disproportionately low in gold and silver, but this is truly floating material, whereas the cathode fouling takes place but an inch from the anode and the bottom of a cathode is known to be more foul than the top.

It may also be well to point out here that satisfactory samples cannot be obtained by drilling cathodes. In the first place, individual cathodes are irregular in purity, but more important is the fact that such samples always show too low results for impurity. This is due to the fact that adhering slimes are usually the nuclei of nodules forming rough deposits and it is necessary to take a relatively smooth part of the cathode in order to drill a hole. Nodules broken off and melted will often show ten times the impurities contained by a drilled sample of the body of the cathode. For these reasons it is necessary to fall back on melted samples or fire-refined cathodes in spite of the accompanying disadvantages, when undertaking work of this character.

The next element on which abundant data are available is arsenic, the ancient, but long since subdued, enemy of copper refining. It was early found that the presence of arsenic in an electrolyte was detrimental to the conductivity of the cathodes. A table is given in the paper for the average monthly value of arsenic in the electrolyte and the conductivity of the wire bars of one of the refineries for a year. The figures of this table are plotted in Fig. II, which clearly shows their correspondence.

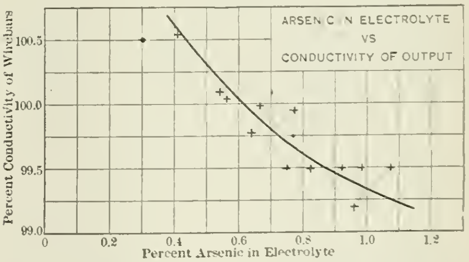

FIG. 2—ARSENIC IN ELECTROLYTE VERSUS CONDUCTIVITY OF OUTPUT

The same relation can be established by direct comparison of arsenic in electrolyte and in wire bars. In another table in the paper figures over a long range of time and for several plants, A. B. C. D., have been grouped, in some cases by periods and in some by classes. These figures plotted in Fig. 3 indicate an arsenic content in the wire bars of 0.0013 per cent when there is no arsenic in the electrolyte, which should be a measure of the fouling due to slimes. Anything above 0.0013 per cent would be due to either inclusion of electrolyte or electrolytic deposition of arsenic. Included electrolyte should vary directly with the composition of the solution, other things being equal. On the other hand, electro-deposited arsenic should increase with the voltage. Now plant C runs at very high current density and therefore at correspondingly high voltage, but no corresponding increase in arsenic in the wire bars can be noticed.

The figures, therefore, might seem to indicate inclusion as the chief source of fouling above the slimes minimum. These Great Falls figures (plant C), by the way, have since been summarized in a paper by Mr. W. T. Burns, Superintendent of that refinery, presented before the American Institute of Mining Engineers last year.

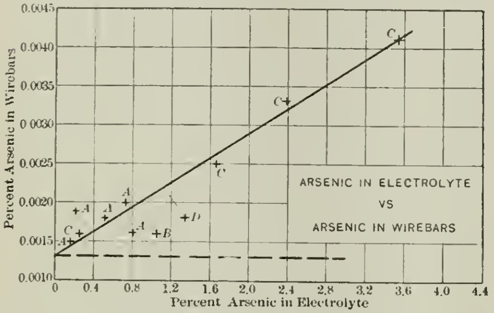

FIG. 3—ARSENIC IN ELECTROLYTE VERSUS ARSENIC IN WIREBARS

We may now turn to nickel for further light on this subject. Here we have an element whose sulphate has a very high decomposition voltage and it would seem unlikely that any nickel at all, regardless of the voltage, could be electro-deposited from a strongly acid solution. Table II gives results from nickel from various sources.

TABLE II.

| Plant | Representing | Per cent Ni in Electrolyte | Per cent Ni in Wirebars |
|---|---|---|---|
| A | 1909 | 1.95 | 0.0041 |
| A | 1910 | 1.60 | 0.0055 |
| A | 1911 | 1.73 | 0.0066 |
| A | 1912 | 1.32 | 0.0038 |
| A | 1913 | 1.78 | 0.0037 |
| B | 10 months | 0.973 | 0.0045 |
| C | Rough figures | 1.00 | 0.0016 |
| D | 1 lot | 0.594 | 0.0014 |

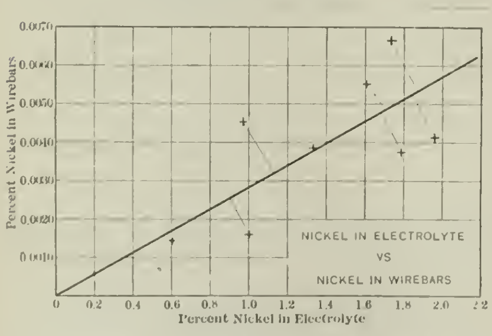

FIG. 4—NICKEL IN ELECTROLYTE VERSUS NICKEL IN WIREBARS

These figures when plotted in Fig. 4 indicate a straight line relation, as in the case of arsenic, but with no nickel in the cathodes when nickel is absent from the electrolyte. In other words, there is no fouling from the slimes. This may easily be so, as the slimes usually carry much less nickel than shown in Table I and even there the possible fouling is but 15 per cent. Further, this nickel is probably present as nickel oxide which is slowly soluble in electrolyte and float slimes may be largely cleansed of their nickel by the electrolyte. The surprising thing, however, is the large amount of nickel found in the cathodes. While a rise of 1 per cent in the content of the electrolyte shows in Fig. 3 a corresponding rise in the wire bars of but 0.0009 per cent, in the case of nickel it shows 0.0028 per cent, or three times as much. Emrich found the same thing. He says: "The large difference shown between the calculated and the observed values of nickel in the cathodes, is a mystery which I have been prevented from investigating."

Either a large quantity of arsenic is removed in the refining furnace, or we must accept electrodeposition of nickel, as the included electrolyte must be rigidly equivalent in the two cases. Those who have tried eliminating traces of arsenic in a refining furnace, except by the use of lime and soda ash or similar fluxes, which is done only in special cases where undesirable quantities of arsenic are present, will lean toward the nickel deposition explanation.

Some laboratory experiments indicated that while no nickel can be deposited from a pure acidulated solution of nickel sulphate, traces can be found in the cathodes when arsenic is added to the electrolyte, which suggests some ion based on the known affinity of nickel for arsenic. Also in an electrolytic separation of copper and nickel by the Hybinette process where the electrolyte was very high in nickel sulphate, copper containing as much as 0.1 per cent nickel has been produced. While these conditions are far from those obtaining in a copper refinery, the results greatly strengthen the deposition argument.

Finally we can examine the inclusion argument on the basis of the specific gravity of cathode copper. If from Fig. 3 a cathode runs 0.0022 per cent, minus 0.0013 per cent (due to slime) equals 0.0009 per cent arsenic due to inclusion of electrolyte running 1.0 per cent arsenic, the cathode would contain 0.0009 times 100 or 0.09 per cent of electrolyte of a specific gravity of let us say 1.15. As copper has a specific gravity in the neighborhood of 8.9, the amount present by volume would be 0.09 times 8.9 divided by 1.15, or 0.7 per cent, which is a measure of the porosity of the cathode. The specific gravity of the copper would be correspondingly diminished, but the amount would be so slight that the known facts do not contradict it. Cathode copper actually shows a specific gravity of about 8.9 similar to worked cast copper, but, on the other hand, we know that cathode copper is very hard—experimental work on direct production of electrolytic wire has given considerable trouble from wear on the dies—and we should therefore expect to find it denser than any other copper if it were absolutely non-porous.

We therefore arrive at about where we started, believing that slimes, included electrolyte and direct deposition all have a hand in the fouling of cathodes, but without being able to assign definite values to each. The relation between arsenic and nickel in electrolyte and in wire bars does seem to be reasonably established and this is of some practical value.

In a communicated discussion, Prof. Wilder D. Bancroft suggested that the fact that nickel is deposited with the copper to an extent increasing with the concentration is probably due to the fact that copper and nickel form a continuous series of solid solutions.

Dr. W. R. Whitney commented very favorably on Mr. Addicks' paper and emphasized the enormous extent to which the electrical industry is indebted to electrolytic copper refining, because of the high economy of a high-grade copper in certain types of apparatus.

### Electro-Analysis of Nickel

The electrolytic determination of nickel was the subject of a paper by Dr. W. JUDSON MARSH, of Cornell University. The paper points out a lack of accuracy in Classen's method and describes a new method which is quite exact.

The solution is made up as follows:

Nickel present (about 0.2000 g.) as $(NH_4)_2SO_4.NiSO_4.6H_2O$.

Ammonium hydroxide 15-20 cc. (Sp. g. 0.96).

Ammonium sulphate 5 grams.

Amperage 0.8 ± 0.1.

Potential difference 3.5 ± 0.2 volt.

Time required about 25 minutes. Room temperature.

Nitric acid, nitrates, and chlorides must not be present. Total volume of solution made up with $H_2O$ to 200 cc.

Electrolyze in a 350 cc. beaker using a 10-g. platinum wire gauze flag anode (52 mesh and 6 x 4.5 cm.) and a rotating (550-650 r.p.m.) pure Cu gauze (50 mesh and 5 cm. high x 3 cm. diameter) cathode. This electrode combination is much less expensive than the Classen dish and disk of platinum, requiring only one-fifth as much platinum as the latter. The Cu wire gauze cathode can be made easily, quickly, and cheaply. Stiff, twisted Cu wire is used for the stems and small Cu tacks are used to rivet the gauze together. One such cathode can be used for a great many determinations, as a fresh surface for deposition may be obtained by clipping a used cathode in 1:1 $HNO_3$ for a few moments. When well made and properly handled the cathodes which cost but a few cents and a few minutes work give results exactly as good as any platinum cathode. This makes it possible to run many more determinations than is usually possible with more expensive forms of apparatus. These cathodes have also been used successfully in the laboratory for the determination of copper, tin, cobalt, cadmium, bismuth, silver, and zinc. They have also been used in combination with the platinum wire gauze anodes for the determination of lead and manganese, both of which are deposited on the anode as peroxides.

In the discussion Prof. Francis C. Frary agreed that the new method, which is a modification of that of Fresenius and Bergmann, is easy and accurate. He stated that it is not necessary to rotate the cathode.

### Quantitative Determination of Radium

Prof. HERMAN SCHLUNDT, of the University of Missouri, contributed a paper on "some experiments on the quantitative discrimination of radium."

The accurate determination of radium in radium-bearing ores is generally conducted by the emanation method. With proper care the method is very certain and delicate. It is based upon the fact that the gaseous disintegration product of radium, the emanation, can be completely separated from radioactive materials, and that the equilibrium quantity is proportional to the content of radium. The minute quantities of radium emanation concerned in quantitative determinations of this kind are capable of exact measurement by electrical methods. The emanation is introduced into an air-tight electroscope or an ionization vessel connected with an electrometer, and the saturation current produced, under proper conditions, is proportional to the quantity of radium in the specimen from which the emanation was separated. The measuring instruments are standardized by means of known quantities of emanation from a standard radium solution, or from weighed amounts of uraninite or some other uranium-bearing mineral not of secondary origin, whose uranium content is known. In standardizing electroscopes by the latter method the radium content of the mineral is obtained by multiplying its uranium percentage by the proportionality factor $3.4 \times 10^{-7}$.

In the assay of radium ores the complete separation of the emanation from the specimen under examination is of course absolutely essential for accurate work. The collection and subsequent transfer of the gas is largely a matter of careful manipulation. The work of various investigators has shown that heating even to a white heat rarely expels all of the emanation from solids. The emanation, however, is completely liberated from the ore by dissolution and boiling. For substances soluble in water or acids several forms of apparatus for the quantitative separation of the emanation have been described.

Rocks and minerals that do not dissolve in acids upon heating, or are only partially soluble in them, require different treatment. One of the standard methods, known as the solution method, consists in fusion of a definite quantity of the material with four to five times its weight of mixed carbonates of sodium and potassium. The fused mass is lixiviated with water and washed with dilute sodium carbonate solution. The insoluble residue is dissolved in dilute hydrochloric acid. The alkaline and acid solutions are placed in separate flasks which are corked. On standing for a month the equilibrium quantity of emanation is again produced by the radium in solution. The emanation is then separated by boiling, and transferred to an emanation electroscope, and after three hours, when the activity is a maximum, the saturation current is measured.

Recently Joly and others have introduced fusion methods which appear to be more reliable than the solution method. The emanation is released from the rock by fusing it with a suitable flux—mixed carbonates of sodium and potassium are generally used—in a closed, electrically heated furnace at a temperature of over 1000 deg. C. The liberated emanation is collected, and after being freed from carbon dioxide, is transferred to a standardized electroscope for measurement.

The results obtained by the fusion method are generally higher than the values by the solution method. In the solution method it is difficult to avoid the formation of slight precipitates in the solutions, and these doubtless cause the separation of some radium, which does not release its emanation completely upon boiling.

The author has investigated several fusion methods and his chief results are as follows:

The solution method, that is, fusion with mixed carbonates, followed by solution and boiling, gave results that are only 70 to 80 per cent of the values obtained by the fusion method with mixed carbonates.

Fusion with mixed carbonates appears to be superior to fusion with potassium acid sulphate, although with the carnotite concentrate a slightly higher value was obtained with the sulphate.

Fusion with borax probably gives low values as a result of the retention of some of the emanation in the melt. At the temperatures attained in our experiments the evolution of gas and its flow through the melt is necessary for complete release of the emanation.

High emanating power in the cold indicates a large release of emanation by heating. In the case of the specimen of carnotite ore a rough assay may be made by merely heating the ore to bright redness.

A complete separation of the emanation from uraninite is obtained by solution in nitric acid and by fusion with some of the ordinary fluxes.

Dr. S. L. Lind (of the Bureau of Mines, Denver) stated in a communicated discussion that incidental to a determination of the radium to uranium ratio in carnotites he and Whittemore studied the quantitative de-emanation of carnotite in a large number of samples of ore by four different methods. As regard the method of fusion with $Na_2CO_3$ and $K_2CO_3$ mixture and subsequent dissolution and decomposition of the residues in dilute acid, they agree with Schlundt in obtaining results 10 to 20 per cent low. The method of dissolving directly in boiling 1-1 $HNO_3$ they found to give correct results, as indicated by the Ra to U ratio, and also by agreement with a direct ignition method, employing Jena glass and Meker burner, and they place the highest confidence in these two methods for this ore. With respect to the carbonate fusion method, they have failed in all carnotites to obtain anything approaching complete de-emanation which result they have been inclined to attribute to the influence of silicates on the viscosity of the melt, because they have successfully employed the same procedure for pitchblende and crude sulphates containing little or no silica. Dr. Lind emphasized that a method may be highly specific in its applicability to a given radioactive substance. For example, the ignition method is successful with carnotites, but a complete failure under the same conditions for crude sulphates, while the fusion method succeeded with pitchblende but failed with carnotite.

Mr. Warren F. Bleecker agreed that the measurement of radium is essentially an indirect method quite difficult to make and is little understood except by experts. What is needed is a method which is easily worked and reasonably accurate. The situation is rendered difficult by the fact that a method once successful is not applicable to all classes of ore without previous examination. The ratio between uranium and radium, only holds in whole rocks—not in works which have been in any wise treated, either mechanically or chemically. Mr. Bleecker exhibited samples of uranium carbide, made in the electric furnace. The substance is of great interest as it is probably the grandparent of radium. Uranium carbide has remarkable properties, not yet fully understood.

Mr. W. R. Mott asked Mr. Bleecker whether he had any trouble from poisoning since uranium was one of the most poisonous materials we can get within the body.

This remark started a lively controversy. Mr. Mott based his claim on the statements of French scientists. Mr. Bleecker combated most seriously any notion there might be as to the poisonous effect of uranium, on the basis of his experience of working with uranium ores and uranium salts on a large scale for several years. Of course, there is dust and that is bad, but there are no poisonous effects.

The result of the discussion was the appointment of a committee, consisting of Messrs. W. F. Bleecker, W. R. Mott, and A. R. Ledoux, to get at the facts as to the poisonous effects ascribed to uranium and vanadium.

### Silicidized Carbon-Silfrax

The first paper of the Friday afternoon session was presented by Mr. F. J. Tone, of the Carborundum Company, Niagara Falls, N. Y., on "Silicidized Carbon-Silfrax."

When solid carbon is acted upon by vapors of silica or silicon there is formed a silicon carbide product of the same shape as the original carbon but differing from carborundum in essential characteristics. To distinguish this form of silicidized carbon commercially, it has been given the name "silfrax." The properties and characteristics of the product vary with the temperature of formation. If the carbon article is heated in the amorphous zone of a carborundum furnace the temperature range of this zone being 1550 to 1820 deg., the product is amorphous in appearance, showing no crystals except under high magnification. It has a yellow color and a lusterless fracture. If the carbon is heated in the crystalline zone of the furnace, the temperature of this zone ranging from 1820 to 2220 deg., the material is of great density and plainly crystalline. Upon fracture it shows a steel black color and a metallic luster.

The depth of the silicidizing action is mainly a function of the time of reaction and the concentration of silicon vapor present in the furnace atmosphere. To obtain the best conversion a large excess of silicon vapor must be present and the mixture should contain silica largely in excess of the theoretical carborundum mixture. Under regular conditions with articles of pure carbon the maximum penetration is about ½ inch. Articles composed of a mixture of carborundum and carbon can be readily converted to a greater depth.

Chemical analysis of the two varieties made in the amorphous and crystalline zones show that both are silicon carbide and give no basis for regarding the products as new compounds of silicon and carbon. Microscopical examinations show in all cases the presence of the typical hexagonal crystals of silicon carbide.

Analyses of Silfrax

| | I | II | III | IV | V |
|---|---|---|---|---|---|
| SiC | 93.33 | 91.03 | 93.39 | 96.86 | 94.19 |
| $SiO_2$ | 1.14 | 4.63 | .75 | 0.94 | 3.10 |
| C free | 1.71 | 1.16 | 2.42 | 0.00 | 0.48 |
| Fe and Al | 3.84 | 3.94 | 2.07 | 1.42 | 1.62 |

I. Silfrax silicidized in amorphous zone of carborundum furnace.
II. Silfrax silicidized on edge of crystalline zone of carborundum furnace.
III. Do.
IV. Silundum.
V. Do.

Analyses of the SiC residue show it in all cases to consist of silicon and carbon in exact atomic proportions for SiC, and there can be no doubt that silicidized carbon by whatever name it may be called is silicon carbide.

Mr. Tone's paper then gives a number of interesting micrographs showing sections of carbon rods heated in both the amorphous and crystalline zones of the solicidizing furnace.

When carbon articles are subjected to the action of silicon vapors and molten silicon for a sufficient period the carbon is silicidized in the same manner as articles placed in a carborundum furnace, but the resultant product is carborundum containing varying proportions of pure silicon. Carborundum and silicon appear to be mutually soluble in all proportions and the physical and electrical properties of the carborundum are altered by the presence of silicon. A carbon block subject to this action in a silicon furnace furnishes a very suitable subject for investigation. Starting from the interior, which is unconverted carbon, the following zones are found:

(1) A greenish yellow product (*E*) not of great toughness and readily crushed down to the constituent grains, which are of great hardness. It is a poor conductor of electricity. On treatment with HF and $HNO_3$ a bright yellow residue is left, which is perfectly crystalline and contains no amorphous material. Even the smallest particles under high magnification are crystalline and practically colorless.

(2) A uniform dense gray product (*F*), having a non-crystalline appearance, very hard, tough and difficult to fracture. Treatment with HF and $HNO_3$ leaves a yellow crystalline material identical in appearance and properties with product *E*.

(3) A coarsely crystalline product (*G*), silver gray in color, very hard but more readily fractured than product *E*. The residue from treatment with HF and $HNO_3$ is mostly yellow, but contains some dark grains and is entirely crystalline.

| Product F | 2.88 | .... | 1.8 |
| Product G | 3.10 | 3.16 | 9.3 |

Mr. Tone showed micrographs made from products *E* and *F*.

In discussing the difference between silfrax and ordinary carborundum, it is necessary to consider the reactions of the carborundum furnace. The reaction of silica and carbon is one which under varying conditions may be made to give a variety of products. Silicon carbide, silicon, silicon monoxide, siloxicon, graphite and modifications or mixtures of these may all be produced by variations in the mixture proportions of silica and carbon, temperature, pressure, rate of energy expended and other factors. In the carborundum furnace, carborundum is initially formed by the reaction of silica vapors on carbon beginning at a temperature of 1550 deg. The first carborundum so formed is always associated with silica and may be regarded as a definite compound, as siloxicon, or as a mixture or solid solution of silica and silicon carbide. Whatever may be its composition when treated with HF and $HNO_3$ it is freed from silica and silicon, the residue being silicon carbide usually in the amorphous state.

At a higher range of temperature complete conversion occurs in accordance with the equation:

$$SiO_2 + 3C = SiC + 2CO \qquad (1)$$

On this equation is generally based the chemistry of the carborundum furnace, but as a matter of fact another reaction plays the most important part in the formation of carborundum and is here offered as a theory to explain fully all the phenomena of the furnace. Equation (1) explains only the conversion of carbon particles into carborundum *in situ*, the crystals or aggregates so formed being no larger than the original carbon particles. It is impossible to explain the growth of large crystals or crystals appreciably larger than the original carbon particles, unless it be granted that both the carbon and silicon when combining to produce these crystals are in the form of vapor. The largest and most perfect crystals are found in cavities or spaces where carbon and silicon in some form of gas or vapor have commingled and combined to form the solid crystals. Such form of carbon, however, cannot be vaporized carbon because it is well known that, at the temperature and vapor pressure of the carborundum furnace, carbon has no appreciable vapor tension. This is further proven by the fact that the effect of high temperature alone is to decompose carborundum, the silicon being vaporized and the carbon being left in a skeleton of the exact form of the original carborundum crystal.

If the vapor tension of carbon were appreciable these graphite pseudomorphs would not retain the perfect shapes of the corborundum crystals so generally observed. The theory is untenable, therefore, that carbon vapor and silicon vapor unite to form the large crystal growths.

To explain fully all the phenomena of the furnace the following reaction is necessary, the reaction being reversible: $2CO + 3Si = 2SiC + SiO_2$ (2)

Carbon monoxide and vapors of silicon and silica are known to be present throughout the furnace atmosphere, and equilibrium relationships and the direction of the reaction in equation (2) depend on the temperature, pressure and the concentration of the reacting substances. The direct reaction is the low temperature reaction and is exothermic. It occurs throughout the crystalline zone, and on it is based the building up of the large crystals from the small crystals formed by equation (1). The reverse reaction occurs in the hottest part of the furnace and next to the core, and explains the phenomenon of the local disappearance of carborundum. This is observed in the rounded formation of the crystals next to the core, which have lost their sharp outline on account of being washed by the silica vapors. It is further observed in the smooth channels and blow holes cut through masses of crystals by the blowing out of the furnace gases. That carborundum can be decomposed or oxidized by silica is well known and is one of the methods of producing silicon.

Reaction (2) further explains the phenomenon of the recrystallization of carborundum first discovered by FitzGerald. Recrystallization can only occur in an atmosphere of CO, $SiO_2$ and Si. It is impossible to recrystallize carborundum in a pure atmosphere of CO by the action of heat alone.

Applying these considerations to silfrax it will be seen that it differs fundamentally from ordinary carborundum in its mode of production. It is produced mainly in accordance with equation (1), that is from the action of silicon vapors on carbon *in situ*, and not from gaseous carbon compounds. The crystals composing silfrax, therefore, are very small and closely aggregated. The development of large carborundum crystals requires free space for the circulation of gases. The largest and most perfect crystals in the carborundum furnace are produced in cavities resulting from the settling of the charge and these cavities are located at a point on the temperature gradient representing approximately the equilibrium temperature for equation (2). In producing silfrax the density of the carbon article is such that when the initial coating is formed the pores are almost completely filled with SiC, making the further circulation of gases very slow and difficult. Reaction (2) which is vapor reaction cannot occur to any extent and the crystals remain small and closely compacted. Silfrax is a crystalline aggregate while ordinary carborundum is a crystal or crystal aggregate.

To this is due the superior toughness and mechanical strength of silfrax.

The commercial applications of silfrax are as refractory materials, electrical heating elements and chemical ware. It has all the chemical and heat resisting properties of carborundum and in addition great density and toughness. Heretofore the articles produced have been of small size. Pyrometer tubes are now made 24 inches in length, and by special furnace construction it will be possible to make much larger sized articles for special refractory vessels and chemical apparatus. It has not yet been determined whether the material can be produced of sufficient density to be used as acid evaporating vessels, for which its very low coefficient of expansion and high thermal conductivity specially adapt it.

In the discussion which followed Dr. C. B. Thwing asked as to the suitability of silfrax for pyrometer tubes, as they should be superior to porcelain tubes, being more refractory and better heat conductors. He asked as to their permeability for gases. Dr. Richards asked whether silicon might vaporize which would attack the couple.

Mr. Horace W. Gillett replied that he had used silfrax tubes for a pyrometer for molten brass. The silfrax tubes may be plunged into the brass without danger of cracking. But at the temperature of yellow brass the tubes are not sufficiently gas-tight to allow a satisfactory use of the pyrometer as yet. There is needed an impervious inner coating for the tubes.

The further discussion centered chiefly around Mr. Tone's new theory of the formation of carborundum and especially its fundamental assumption that carbon has no appreciable vapor tension at the furnace temperature.

Mr. F. A. J. FitzGerald did not think that this has been proven or that it is generally admitted. He described a number of interesting experiments he had made on reactions between carbon tubes with silica or silicon, inside or outside, and from them he drew the conslusion that in explaining the phenomena in a carborundum furnace it is better to work on the hypothesis that we have appreciable vapor pressures not only of silica and silicon, but of carbon and silicon carbide. In any case before that hypothesis ceases to be useful, we need more experimental evidence than has so far been disclosed.

Prof. Jos. W. Richards referred to a method for calculating approximately the vapor pressure of carbon. He finds that at 1730 deg. C. there will be as large a vapor tension of carbon as there is of zinc in the sherardizing furnace. Since in the latter case zinc is plated out commercially, there is good reason for supposing that the tension of carbon vapor can play a very appreciable part in the reaction of the carborundum furnace.

Mr. F. A. Lidbury asked whether in the paper absolute conclusions had not been drawn in cases which admit of several interpretations.

Mr. W. R. Mott thought that at the temperatures in question the vapor pressure of carbon must be extremely small, because otherwise there could be no carbon-filament incandescent lamp.

Dr. W. C. Moore suggested that the graphite tube used in one of FitzGerald's experiments might have absorbed oxygen which might have been a disturbing factor in the results.

Mr. Tone stated that according to a calculation of Sir William Crookes carbon has zero vapor tension at 2700 deg. C. Very important experimental evidence is to be found in the graphite pseudomorphs obtained in the decomposition of carborundum by heat, the silicon being vaporized and the carbon being left in a skeleton of the exact form of the original carborundum crystal. They retain not only their crystalline outline, but the markings, workings, and spirals that often occur on the faces of these crystals. Mr. Tone thought that Mr. FitzGerald's experiments were not carried out in a way so as to exclude completely oxygen.

Mr. Alfred H. Cowles referred to some early experiments made by him.

### Electrolytic Insulation of Aluminium Wire

A paper on this subject by C. E. Skinner and L. W. Chubb, of the Westinghouse Company, was read by Mr. Skinner.

Any gain in the efficiency of electric conducting material must be obtained by increasing the conductivity or decreasing the thickness of the insulation. The authors have found that it is possible to produce an insulating coating on the surface of aluminium wire which is so extremely thin that on many of the smaller sizes of wires it is possible to get a higher space efficiency, so far as the conducting material is concerned, in a coil with aluminium than with copper, even when the thinnest possible insulation is applied to the copper.

The skin or thin layer of natural oxide which is so objectionable in the soldering of aluminium is a nonconductor of high dielectric strength and the authors have developed a method of strengthening the coating by means of an electrolytic action which produces a coating of many times the dielectric strength of the coatings which has been obtained by former methods.

The various arrangements of apparatus which were devised in the development of the process are described in the paper. In the last one developed the wire passes straight through five tanks, of which the first and last contain hot water for washing and the middle three electrolyte. Solutions of borax, ammonium borate and sodium silicate are suitable electrolytes, the last being the best of the three.

The speed of treating wire varied from 40 to 150 feet per minute for the different sizes of wire used and the consumption of energy was from 0.15 to 0.80 watt hours per square inch of surface treated.

The insulation formed by the above is a thin film of alumina which is smooth and iridescent or abrasive and white. The smooth films form with a greater expenditure of energy and in inferior electrolytes. The white film formed in sodium silicate at about 425 volts is rather smooth to the touch, but so abrasive that it cuts and grinds the hand while coil winding. In some cases this treated wire running through the hand of the winder has cut through the skin and into the flesh before discovery.

The dielectric strength is far superior to the oxide coat formed by the former methods, for instead of standing a maximum of 0.5 volt two wires electrolytically treated and twisted tightly together without abrasion will stand from 200 to 500 volts.

The thickness of the film is apparently variable. Tests of change in diameter of wire before and after treating and tests of reduction in metal section by resistance measurements before and after treating show the coating to be from 0.0001 to 0.0004 inch (0.00025 to 0.001 cm.) thick.

On account of the thinness of the film it is quite flexible and does not open or appreciably weaken by sharp bends and kinks in the wire. Soft wire can be stretched 30 per cent of its length without apparently injuring the insulation. Two wires at a potential difference of 250 volts can be crossed and pressed together at the intersection until the wires are dented to such an extent that the intersection is no thicker than a single wire. If there is no relative motion between the surfaces in contact the insulation will not break down, but the slightest movement of one of the wires will cause a grinding between the surfaces which will at once cause a short circuit.

The insulating coating is fireproof and has sufficient strength mechanically to support the wire in small coils when the metal is above the melting point. Small coils run with the wire molten will fall to pieces if the current is suddenly stopped, but if the current is gradually lowered the metal will solidify and remain intact.

Electrolytically insulated aluminium wire is suitable for many classes of work requiring wires of relatively small size where the insulation requirements are not excessive and particularly where temperature requirements are severe. The very small sizes, No. 30 B & S Gauge and smaller, cannot be satisfactorily used on account of the difficulty in drawing the wire and in subsequent handling. In the very large sizes there is no advantage in the use of aluminium wire where the space is restricted. This wire has been found particularly advantageous for use in coils which require light weight and which are subject to relatively high temperatures, provided the insulation requirements on the individual wires are not excessive. The weight of an aluminium wire coil is from 40 to 50 per cent of that of the equivalent copper coil. The thermal capacities of the two types of coils are practically the same and the temperature coefficients are equal. The heat dissipation through the aluminium coil is found to be slightly better than the equivalent copper coil.

While this new wire has limitations, it has a decided sphere of usefulness, which will probably be greatly extended, particularly in the event of the ratio between the base prices of aluminium to copper being decreased.

The paper was discussed by Mr. W. R. Mott and Mr. H. M. Hall, who had used such a process on square aluminium wire. In order to get satisfactory results at the edges he had to draw the edges rather blunt; it was still square wire, but the edges were appreciably rounded. Mr. Skinner replied that it is a fundamental principle in electrical work not to use wire with sharp square edges.

### Electropercussive Welding

A paper on this subject by C. E. Skinner and L. W. Chubb, of the Westinghouse Company, was presented by Mr. Chubb.

In the development of the process of electrolytically insulating aluminium wire (described in the preceding abstract) it was found that the making of joints in the wire itself was a serious problem. It was solved by developing the process of electropercussive welding. Two wires are welded together by causing a condenser discharge to pass between the ends of the wires in the moment when they are pressed together by mechanical force.

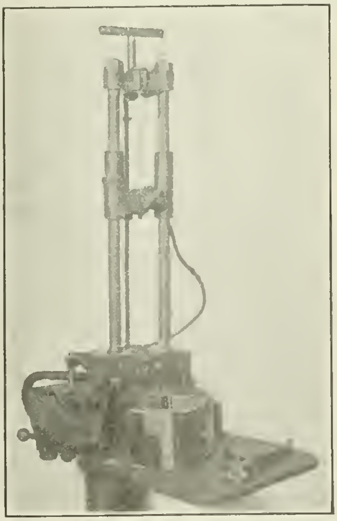

FIG. 5—APPARATUS FOR ELECTROPERCUSSIVE WELDING

Fig. 5 shows a portable tool of the gravitational type set to attach a copper lead wire to a coil of aluminium wire. The welding circuit (Fig. 6) consists of a direct-current line, or a generator *G* which charges an electrolytic condenser *C* through a high resistance *R*. Adjustment of the voltage of the charged condenser is obtained by field control of the generator or by varying the resistors *R* and *R'*. The wires *WW* to be welded are secured in the wire grips of the welding tool which are connected to the terminals of the condenser through an inductance *L* of from 2 to 10 turns of cable. A spring switch *S* with carbon contacts, normally held closed is connected across the jaws of the welder so that their potential difference will be zero while the wires are being put in or the finished product is being removed. The welder is connected to the auxiliary apparatus by means of long flexible cables which allow welding within a radius of about 50 feet without moving the condenser and without any other heavy apparatus.

The process of welding is as follows: The wires are secured in the wire grips and the ends cut off as short as possible with a suitable pair of cutters. The switch *S* is then opened which charges the condenser to the proper voltage, a catch is then released which lets the sliding member fall and bring the ends of the two wires into percussive engagement. At the instant of contact, the short circuit current of the condenser builds up to such a value that the ends of the wire are melted by the explosive discharge and instantly forged together by the blow of the falling mass. The weld is then complete and after being removed from the machine will be found to have the strength of the original wire.

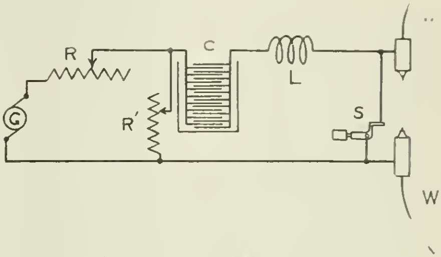

FIG. 6—ELECTROPERCUSSIVE WELDING

The generation of the heat is so localized, so sudden and so intense, that there is no time for unequal heat conduction through the shanks of the wire and the ends will be melted and even vaporized whether the melting point is high or low. For this reason metals of different kinds can be welded together independent of their electrical resistance, melting point or heat conductance. Any combination of metals which has ever been tried will weld together, but the joints will not be permanent with such combinations as aluminium and tin, or lead and iron.

Electrically the weld is complete in 0.0012 second and although 23 kilowatts are being dissipated between the ends of the wire at a certain instant, the total energy used at the weld is about 0.00000123 kilowatt-hour or enough to light an ordinary 50-watt, 16-candle-power lamp for 0.09 second.

Many of the alloys of most metals are very hard and brittle. As an example, there are alloys near both ends of the copper-aluminium series which are unworkable, and yet electro-percussive welds between these two metals are so ductile that they may be worked in a die, forged, or rolled into thin foil. Any alloy formed at the weld must range from 100 per cent copper on one side to 100 per cent aluminium on the other; but possibly the brittle combinations are so thin that the joint as a whole is flexible and ductile. This joint between aluminium and copper is of great importance, as copper lead wires, which solder and connect easily, can readily be attached to aluminium coils. At first it was feared that a diffusion of the two metals in service would finally result in a brittle joint, but tests show that after four years the joints are practically as strong and ductile as when first made. Similar ductility has been noted in almost every combination of metals when first welded, but diffusion, disintegration and loss of ductility eventually result in such welds as silver to tin, or aluminium to tin.

Metals which are either hardened or softened with heating and sudden cooling can be welded together without appreciable change in the physical properties of the material. Tempered spring steel welded, reduced to uniform diameter, and tested has shown equal or greater strength at and near the weld without any noticeable change in temper. Metals such as hard drawn copper, silver, aluminium, etc., which soften with heat can be welded together without causing any local annealing, and these metals and steel when soft can be welded together without detrimental local hardening.

This type of weld offers a very convenient specimen for the study of the diffusion of different metals at different temperatures and under various other conditions. Micrographs were given showing copper-platinum and copper-silver respectively. Both of these welds show a sharp dividing line at 1000 diameters. While the apparatus up to this time has been made only for the welding of wires, 0.072-inch diameter and smaller, the application to larger sizes is merely a question of the design of suitable apparatus.

### Electroplating

A paper by Prof. W. Lash Miller, of Toronto University, dealt with "the formation of a badly conducting film on copper anodes in copper cyanide solution."

While preparing some experiments for the laboratory of the Toronto Branch of the American Electroplaters' Society, a current of about one ampere was sent through a copper cyanide bath (No. 3, below) using strips of copper 9 cm. x 3 cm. as electrodes, the 110-volt direct-current lighting circuit as a source of current, and a 32-candlepower carbon filament lamp as resistance in the circuit. The lamp, bright at first, within a minute's time burned dim, the evolution of hydrogen at the cathode fell off, and a voltmeter set over the cell showed a potential difference of 45 volts. On examination, the anode was found to be coated with a smooth yellow-green adherent deposit; and a few simple trials soon showed that the resistance of this film was the cause of the drop in current.

The formation of such a deposit evidently sets an upper limit to the current density at the anode that can be used efficiently with any given bath; a number of solutions recommended in the literature, which had been made up for another purpose, were tested from this point of view.

It was soon found, as expected, that the current density of which a noticeable film is formed depends on the shape and position of the anode and on the amount of circulation in the electrolyte; the simple apparatus shown in Fig. 7 was then constructed, and the various electrolytes were compared under the conditions obtaining in it.

In the figure, *A* is the anode, a cylinder of copper rod 2 cm. in diameter, *C* is the cathode, a hollow cylinder of sheet copper 2 mm. thick, 4 cm. internal diameter, slit down one side so that the height of the liquid could be read on a paper scale *S* pasted on the outside of the glass container *G*. Anode and cathode were held in position by means of two corks, of which the lower, *L*, was provided with a socket to catch the end of the anode and with notches around its edge to let the solution flow out evenly when the tap was opened. The zero mark of the scale was level with the upper side of the lower cork, its graduations ran from 1 to 10, and gave the area of submerged anode in tenths of a square decimeter; division 10 was 2 or 3 centimeters below the upper cork *U*.

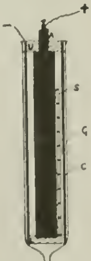

FIG. 7—TEST CELL

To ensure that the liquid would run out of the cell at the same rate in different experiments, a glass nozzle was attached by rubber below the tap, and the latter was always either closed or wide open; with the nozzle used it took the solutions 60 seconds to fall from division 10 to division 1 on the scale, the volume comprised between these two marks being 197 cc.

Before each measurment, anode and cathode were cleaned by nitric acid, washed under the tap, and placed in the container; 250 cc. of an electrolyte was poured in through the funnel, the tap was opened, and as the surface passed division 10, the current (about one ampere) was switched on and its amount recorded. As the level fell, a voltmeter wired across the cell was read; at first the voltage was low, then suddenly began to rise, often with a well marked "jump," whereupon the circuit was broken, the cap closed and the level recorded; hence the current density when the sudden rise in voltage began was calculated. If the tap were left open, and the current on, the voltage rose rapidly until the needle reached the end of the scale.

Tests were made for various solutions and the results given in a table in the paper. Sulphate and carbonate solutions with different amounts of potassium cyanide, potassium and sodium carbonate, and ammonium hydroxide were tested. As a general rule not only cyanide, but ammonia or any other substances that hold the copper in solution, can be added to the bath to permit the use of a high anodic current density.

### Electrodeposition of Lead and Tin

Prof. Frank C. Mathers, of Indiana University, presented a paper on the electrodeposition of lead from lead acetate solutions.

Lead fluosilicate and lead perchlorate baths are the only ones that have been used successfully in lead plating. The great disadvantage or objection to them is that they must be made by special apparatus and by troublesome methods. The actual electroplating with either of them is very easy.

The deposits of lead which were obtained by the electrolysis of lead acetate baths containing ammonium perchlorate and peptone were much better than had been obtained previously from any lead salt of a weak acid. The cathodes were smooth during the first part of the deposition, but as the thickness of the deposit increased the cathodes became more and more rough. All of these deposits were brittle.

As these baths lacked something, the author has now tried various additions agents and has obtained smooth, finely crystalline deposits, much superior to those obtained with peptone as addition agent.

For each liter (1.056 quarts) of bath there should be used 100 gms. lead acetate, 40 gms. ammonium perchlorate, 25 to 50 cc. of glacial acetic acid and addition substance and an addition agent for which five different prescriptions are given. The best is this:

Treat 12.5 gm. of aloes with 500 cc. of warm water and shake until the soluble material has dissolved. Let stand until the insoluble tar or gum settles and adheres to the sides of the vessel.

Dissolve the insoluble tar or gum obtained from the extraction of 12.5 gm. of aloes with water, in the glacial acetic acid. Add this solution to the bath and electrolyze without filtering. No better addition agent than this was found.

A current density of 0.4 amp. per sq. dm. (3.6 amp. per sq. ft.) must be used for thick deposits. For thin deposits in plating 0.8 amp. per sq. dm. may be used. With the higher current density, ammonium acetate cannot be used in place of the ammonium perchlorate.

The current efficiencies at the anode and at the cathode are near 100 per cent. The excellent corrosion of the anodes is proved by the fact that the copper wires attached to the anodes in the solution were not dissolved. The specific gravity of the deposited lead was 11.27.

More of the addition substance and more acetic acid must be added to the bath during the course of the electrolysis.

Prof. **FRANK C. MATHERS** then presented a second paper, written by himself jointly with **BARRETT W. COCKRUM**, on "electrodeposition of lead from lead lactate and lead formate solutions."

This paper gives the details of experiments on the conditions under which a smooth, thick, firm, crystalline but rather brittle deposit of lead can be obtained from lead lactate and lead formate baths.

The baths that gave the best deposits contained 4 per cent of lead as lactate or 2 per cent of lead formate, 1 to 5 per cent of lactic or formic acid, 4 per cent of ammonium perchlorate and 0.25 per cent of Barbadoes aloes.

This mixture was warmed and then filtered in order to remove the insoluble gum which was in the aloes.

FIG. 8—ARRANGEMENT OF FITZGERALD LABORATORIES FOR SYMPOSIUM ON PRACTICAL ELECTROCHEMISTRY

A current density of 0.4 amp. per sq. dm. (3.6 amp. per sq. ft.) was found to be best; with higher current densities the deposit became rougher.

Thick deposits were obtained without difficulty. The specific gravity of this electrodeposited lead was 11.25 and 11.28 for the lactate and formate baths respectively.

Other addition agents were tried in the place of the Barbadoes aloes, but of these peptone was the only one of any marked value.

It was found that sodium naphthalene sulfonate could be used in the place of ammonium perchlorate. Other salts of strong acids did not give as good results as the perchlorate.

The only disadvantages in the use of baths containing lead salts of weak acids are:

(*a*) A low current density must be used.

(*b*) The deposits are brittle as a result of the large amount of addition substances that must be used.

Prof. **FRANK C. MATHERS** finally presented a paper by himself and **BARRETT W. COCKRUM** on "electrodeposition of tin from tin salts of mineral acids." A very extended research was made, but a method giving an entirely satisfactory deposit has not yet been framed. New addition agents are to be tried.

Professor Mathers illustrated the presentation of his papers by various interesting samples of deposits obtained under different conditions.

Messrs. W. Lash Miller, S. S. Sadtler, Francis C. Frary, Jos. W. Richards and G. A. Roush participated in the discussion. The latter pointed out that the density of the lead deposited by Mather is lower than that of cast lead. This is the reverse of the case of copper, electrolytic copper being always higher in density than cast copper.

Prof. J. W. Richards explained that cast copper contains gases which lower its specific gravity, while cast lead does not.

### The Evaporator Problem in Electrochemical Plants

The Saturday morning session was opened by the presentation of a paper, by **OTTO MANTIUS**, on "the evaporator and the power problem in electrochemical plants." The paper is published in full elsewhere in this issue. (See p. 722.)

The paper was discussed at some length by Messrs. A. H. Hooker, L. V. Vorce and E. M. Sergeant. Mr. Vorce referred to a combination of double effect and single effect as a rather convenient form of evaporator operation which should deserve consideration.

The corrosion of the tubes was also the subject of various remarks. Mr. Hooker asked why in the vertical-tube type of evaporator the corrosion should always be in the upper parts of the tubes? If abrasion, why was it not greater in the first than in the second, since there is more salt in the former? Mr. Mantius replied that the speed increases enormously from the bottom to the top; for this reason the salt has a greater wearing action at the top of a tube than at the bottom. The top grows thinner. Also the speed is much higher in the last effect than in the first and second effect.

### Symposium on the Practical Side of Electrochemical Investigation

After the presentation and discussion of Mr. Mantius' paper the whole of Saturday was devoted to a symposium on "the practical side of electrochemical investigation," consisting of "a number of informal demonstrations of apparatus, methods, and materials used in electrochemical investigations or as electrochemical aids to chemical investigation."

FIG. 9—ELECTRIC (GRANULAR CARBON RESISTOR) FURNACE FOR HEATING COFFEE AT LUNCHEON IN TRANSFORMER SUBSTATION

This was an entirely novel undertaking and it should be stated at once that it was a full success and was thoroughly enjoyed by all who attended it.

The attendance was about 150 during the morning as well as the afternoon and the interest never flagged to the end.

The FitzGerald Laboratories where the symposium was held, are ideally suited for just such an undertaking, as they were founded and equipped not only for the development of electric-furnace and other processes (in which line the FitzGerald Laboratories have greatly distinguished themselves), but also for demonstration purposes. Excellent use was made of the power, furnace, and apparatus facilities available in this laboratory. Final success was assured by the esprit de corps of the Niagara Falls electrochemists who had stood together in the careful preparation of the symposium to make it a notable event. As a matter of fact, it went off without a hitch and proceeded exactly according to schedule.

As President Lidbury explained, one principal object of the symposium was to show how one can get along very well quite often in research work with simple home-made appliances instead of highly elaborate special apparatus.

The general procedure was that the man who would make a demonstration would first make a brief speech from the rostrum, explaining what he was going to show. Then the audience would pass over to the place where the demonstration was made, watch it, and finally return to their seats, when a general discussion would be started.

Mr. F. A. J. FitzGerald showed the heating of a carbon rod and the formation of a fused silica tube from sand placed around the carbon rod, with a convenient arrangement of four transformers which can be connected up in different ways for furnace regulation. The formation of carborundum crystals at the contact surface was observed. The matter was of interest in connection with his discussion of Mr. Tone's paper of the day before.

Mr. L. F. Saunders showed a resistance-furnace arrangement useful for melting-point determinations, the charge in the chamber being heated by radiation from a resistor at the top. This resistor is formed by a graphite plate sawed in such a way that incisions are made alternately from either side parallel to the end edges, so as to force the current to pass in a narrow zig-zag path through the plate and heat it. It is used directly on a 110-volt circuit. Such a resistor may be used for some seven or eight heats. Temperatures up to 2200 deg. C. can thus be produced.

Mr. Saunders then showed the behavior of an amorphous carbon tube in short-circuit between graphite blocks in a 50-volt circuit. When the tube heated up, the current increased to 1500 amp.

The construction of wire-wound tube and crucible laboratory furnaces with alundum as refractory was then shown, the method of winding being demonstrated by Mr. J. B. Glaze. Nichrome wire is used as resistor for temperatures up to 1000 deg. C.

Mr. FitzGerald showed a simple construction of a 50-volt 1200-amp arc furnace of the Stassano type with graphite electrodes and demonstrated in it the melting of lime. Vitrocarbon brick was used for the furnace roof.

This vitrocarbon brick is a new refractory brick of the National Carbon Co. As explained by Mr. A. T. Hinckley, this brick stands temperatures up to 2400 deg. C. in a reducing or neutral atmosphere. There is no shrinkage even at high temperatures. Vitrocarbon brick is a little cheaper than high-grade silicocarbide materials. Its heat conductivity is between that of silicon carbide brick and alundum brick. Its electric resistance is 1 ohm per inch cube, but decreases with increasing temperatures. It is an acid refractory.

Mr. Hinckley also showed a sample of a new "heat-insulating refractory brick," which has a heat conductivity 70 per cent of that of standard firebrick at 600 deg. C. and can be used up to 1400 deg. C. It cuts down the heat losses by 30 per cent.

The results of a Seger cone experiment were also shown, silicon brick cones and vitrocarbon brick cones being among the cones tested. The vitrocarbon brick had stood the test best.

Mr. Hinckley then demonstrated the method of measuring the resistance of joints of carbon electrodes screwed together, by the drop of potential method. The potential drop is measured over a length of continuous electrode and over an equal length containing a joint. A special paste of the National Carbon Company permits to reduce very much the power loss in the joint between two threaded electrodes screwed together. The resistance of the joint is equivalent to 3 or 4 in. of carbon without joint. But the use of the special paste brings this figure down to 2½ or 2 in. Rex A tool steel is suitable for shaping, drilling, etc., carbon electrodes.

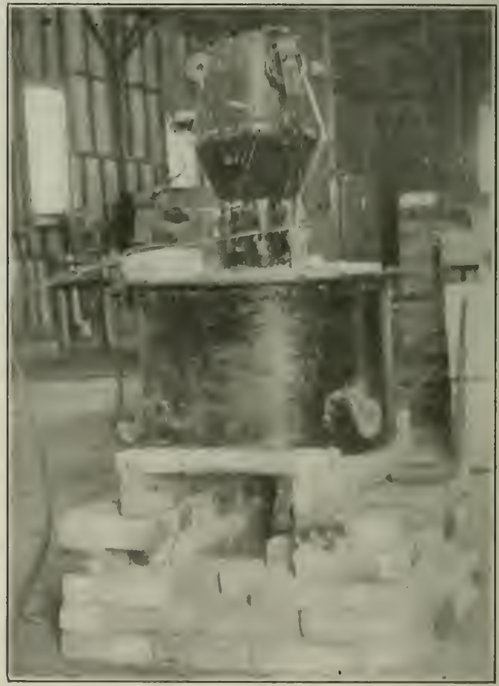

FIG. 10—ELECTRIC FURNACE FOR MELTING TIN DROSS

Mr. E. R. Cole demonstrated the great ease of machining Acheson graphite and the production of the most varied forms of graphite articles for special purposes, for instance, the production of a resistor tube by sawing a spiral curve into a graphite tube, further graphite terminals for mercury-arc rectifiers, etc.

Mr. Dantzisen showed a molybdenum-wire-wound alundum tube furnace of the General Electric Company for temperatures up to the melting point of alundum (about 1900 deg. C.). Oxidation of the wire is prevented by an atmosphere of hydrogen.

Dr. Carl Hering, of Philadelphia, Pa., showed a simple model of his pinch-effect furnace in which he demonstrated the melting of lead, the agitation produced by the "pinch effect" being clearly shown.

This was the last demonstration of the morning session.

Lunch was taken at the nearby Cliff Distributing Company's substation, where among other excellent things coffee prepared on a granular-carbon resistance furnace was greatly enjoyed. The highly original yet simple arrangement is shown in Fig. 9. For this as well as the photograph of the interior of the Fitz-Gerald Laboratories (Fig. 8) we are obliged to Mr. J. Rattray Wilson, electric engineer of Niagara Falls and an amateur photographer of no mean ability.

A visit to a nearby linen factory followed.

In the afternoon session Dr. Hering's pinch effect furnace was first the subject of some discussion. As to the temperature difference between the resistor and the bath, Dr. J. W. Richards estimated that for a viscous metal it might be 100 deg.; for brass it would be hardly 20 deg. As Dr. Hering explained, this temperature difference depends on the viscosity of the metal and also on the pinch force. Barium chloride is not suitable for direct melting in a pinch-effect furnace, but it can be easily melted over a fused bath of lead. In a pinch-effect furnace in Philadelphia a good many tons of brass have been successfully melted.

In the development of the furnace the chief trouble experienced has been with the transformer. The energy of the motion in the furnace is represented by a counter electromotive force in the circuit. This is very favorable, as it allows the use of higher voltages at the furnace and a much easier design. But as it is not known exactly in advance, it may be that it comes out differently from what was expected, and the transformer has to be redesigned. A further transformer trouble is that if regulation is wanted, the power factor is poor.

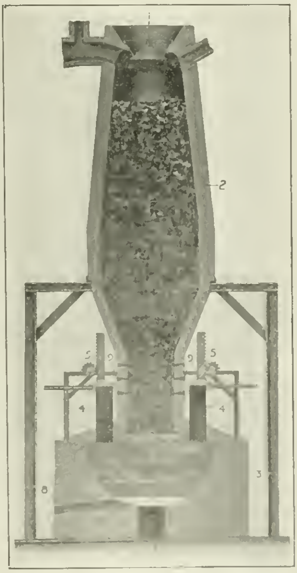

FIG. 11—TIN-DROSS ELECTRIC FURNACE

Dr. Hering stated that there is absolutely no trouble with the resistor holes. They do not wear away. They are made of fused magnesite. The pinch-effect furnace can be used for reduction processes, but slag must not be permitted to get into the resistor tubes. Metal must always stay in the resistor tubes.

Mr. L. W. Chubb then demonstrated the electro-percussive method of welding aluminium wires together, as described in the abstract of his paper given above.

Mr. Raymond S. Wile, of Pittsburgh, Pa., demonstrated his electric furnace for melting tin dross. A view of the demonstration furnace is given in Fig. 10, while Fig. 11 is a diagrammatic sketch of its construction. The charge is fed into the furnace stack 2. The construction is shown for operation with two-phase or three-phase currents, when 4 are the upper electrodes and 6 the bottom electrode. 5 is the gear mechanism for adjusting the position of the top electrode. The upper electrodes 4 do not come in contact with the tin dross being melted and their ends merely dip into the layer of slag. As slag, a layer of molten glass is used which also serves as resistor. The slag level is maintained constant by means of the overflow hole 7. The tin metal is tapped off through 8.

Most of the tin that evaporates is condensed in the column of charge coming down through the shaft. Any tin vapor which should not be condensed is recovered in a down comer. The loss of tin in the slag is only one-half per cent. The total loss by volatilization is 1½ to 2½ per cent, the actual furnace loss from ¾ to 1 per cent of the tin charge.

In the discussion which followed the demonstration Mr. Wile stated that the specific energy consumption was from 600 to 900 kw-hours per ton of tin, depending on the size of the furnace and the consumption of the slag.

Further discussion centered on the starting of the furnace and regulation of temperature. The latter may be done by a transformer with different steps or by varying the thickness of the glass layer.

The furnace has been used not only for melting tin dross, but for melting glass, also brass and other alloys, and for the melting of the precipitates in cyanide plants.

Mr. P. E. Landolt of the Research Corporation demonstrated Dr. Cottrell's electrostatic method of precipitation of dust particles from fumes. Alternating current was transformed by a special synchronous commutator to rectified direct current at 40,000 volts. The demonstration was made successfully with zinc oxide and later with phosphorus fumes.

The latter experiment demonstrated the fact that the design of the apparatus and the voltage required depends on the rate of flow of gas and the amount of dust in unit volume.

The Cottrell process is now in successful use in cement works; for fumes from slime furnaces to recover gold and silver particles (copper refineries); for tin (stannic oxide); for zinc oxides; for lead fumes (Garfield); for lead sulphide from sintering machines (Toeele, Utah); for detarring illuminating gas; for precipitating sulphuric acid mist, flower dust, carborundum dust, borax dust, etc. In the near future the cleaning of iron blast furnace gases will be taken up.

Mr. Hinckley then demonstrated a method for determining the rate of oxidation of electrode materials used for different purposes. This may be determined either at constant temperature or at constant current or at constant voltage. Mr. Hinckley's determinations were made to constant temperature.

At 1000 deg. C. electrodes of equal porosity showed the following losses in grams per square centimeter per minute:

| | |
|---|---|
| Graphitized electrodes.......... | 0.0050 |
| Electrodes for steel furnace..... | 0.0065 |
| Fine-grained electrodes......... | 0.0075 |

Mr. FitzGerald exhibited a tube furnace for melting point determinations in which the tube is embedded in granular carbon which is the resistor. This arrangement heats up less quickly than Mr. Saunders' arrangement shown in the morning, but has a longer life.

A thermoscope, using silver sulphide, was demonstrated by the FitzGerald Laboratories.

A threaded amorphous carbon electrode 20 in. by 84 in., of 1450 lb. weight, was exhibited by the National Carbon Company, the resistivity being 0.0017 ohms per inch cube.

After a hearty vote of thanks the meeting adjourned. The next meeting will be held in the spring of 1915 at Atlantic City, N. J.

## The Hall Process of Desulphurization

In view of the commercial necessity of so operating smelting plants that noxious fumes of sulphur and other elements shall not contaminate the atmosphere, metallurgical experiments along this line have been important and interesting. At the present time the elimination of sulphur dioxide is the most important problem, since other deleterious gases and solids have been pretty well controlled.

At a recent meeting of the New York Section of the Mining & Metallurgical Society of America, Mr. H. F. Wierum gave an account of what has been done with the Hall process, which aims to eliminate sulphur from sulphide ores and mattes without allowing sulphur dioxide to escape, and to recover the sulphur thus eliminated. The following excerpt is made from Mr. Wierum's address.

William A. Hall, the inventor of this process, tested his first ideas at a little place near Paris, called Levallois. He used a small brick-lined circular furnace, 18 in. or so in diameter, with a removable tile top, into which he introduced pyrites and which he heated by a very low-grade producer-gas carrying but 130 B. t. u. per cubic foot. The results obtained in this furnace were important only as an impetus to further investigations. No matter how many pounds of pyrites were treated, or how many cubic feet of gas were used, the tests resulted in a fairly complete desulphurization of the pyrites without yielding any detectable sulphur dioxide; the fumes from the discharge pipe of this furnace apparently consisted of white or yellowish-white sulphur vapor. Steam in small but unmeasured quantities was introduced with the gas through jets placed between the gas burners on the furnace.

These experiments were repeated in a similar furnace, in London, and later in Brooklyn, the gas in both cases being a city product of from 500 to 600 B. t. u. per cubic foot. The results were the same. It should be noted that in these preliminary experiments air was carefully excluded from the furnace, except such air as was blown into the burners themselves, in quantities just insufficient to burn completely the amount of gas introduced. Air was excluded in an efficient manner by maintaining a rather heavy back pressure in the furnace.

Of course, it has long been known that about one-half of the sulphur in $FeS_2$ can be distilled from it by a mere application of heat, about 1300 deg. F., being required to start the distillation effectively. The remaining one-half, however, it has always been contended, cannot be dissociated from its combination with iron, or any other base, by simple heat. With these experiments before him, Mr. Hall drew up his first patent papers and attempted his first theory in the premises, and many a pencil was set busy trying to figure out possible chemical reactions that had apparently heretofore escaped the scientific world.

### Chemical Reactions

Now it is possible to write a reaction which will account for what the eye saw during those short tests, but whether such a reaction actually takes place *I am not prepared to say*, and I trust you will all feel perfectly free to form your own opinions as to the feasibility of such combinations as the following. Let us assume first that about one atom of sulphur has been distilled by heat alone from $FeS_2$, leaving a sub-sulphide of iron, which can be roughly designated as FeS. Now comes the first chemical reaction, whereby six molecules of FeS added to six molecules of $H_2O$ at a suitable temperature are supposed to yield six molecules of FeO and six of $H_2S$. Doubts probably arise at once in your minds as to the ability of any heat obtainable in a roasting furnace to decompose water in this manner. Nevertheless, here was this little furnace—with an air supply insufficient even to burn completely the gaseous fuel used—turning $FeS_2$ into $Fe_3O_4$, and having only the oxygen of *water* available as a stable equivalent for the sulphur in combination with iron. Red-hot iron decomposes water; why not red-hot FeS, or $Fe_6S_7$, or carbon, or red-hot *anything* that we do not know positively will *not* do it? Such were the questions we had to ask ourselves. So we go bravely on, and accuse the little furnace of decomposing enough water to satisfy the second reaction of the cycle: $6FeO + 3O = 3Fe_2O_3$. Following this comes the third chemical process, which I think is quite feasible under suitable conditions, provided the two foregoing reactions can be brought about: $3Fe_2O_3 + 6H_2S$ (if formed) $+ 5O = 2Fe_3O_4 + 6H_2O + 6S$ (free).

It seems fruitless, however, to discuss whether or not any such cycle of reactions actually occurs. I simply wish at this point to leave in your minds one fact, that in the little furnace described above, $FeS_2$, carrying some 48 per cent of sulphur, *was* freed from its sulphur, down to about 5 per cent, by a treatment with producer gas at a temperature of about 800 deg. C., introduced with insufficient air to burn this producer gas completely, and with some steam present, while maintaining such a strong back pressure that no suction whatever existed in the furnace, and no outside air could possibly have been drawn in.

The next step was the construction of a slightly larger furnace, mechanically rabbled, but of the same general design as the little pots just described. The only information gained by this increase in size and efficiency was to obtain a record as to how long the ore was under treatment, and very accurate and continuous data as to the amount of $SO_2$ in the fumes. The result of official tests conducted by two of our most respected and experienced chemists and metallurgists indicated that $SO_2$ was always below 0.1 per cent; that sulphur in the calcines was 3 per cent or under, and that the weight of ore treated per square foot of hearth area per 24 hours was approximately the same as in the regular MacDougal furnace.

Another point was tested in this second furnace. Some chemically pure sulphide of iron was bought, answering the formula of FeS. This contained no feeble atom of sulphur, nor unstable atom, or whatever you wish to call it, and yet this material was decomposed under exactly the same conditions as the pyrites, with practically identical results. In our later trials, this experience with monosulphide of iron, and also with some matte—which roughly answers the formula of monosulphide of iron—has always puzzled me and still does so.

### Commercial Experiments

When the tests had reached this point, I was called upon to carry out certain experiments that had been arranged by the gentlemen controlling the rights to this process, at a large smelter in California which had been closed down for some time. As you see, I had rather meagre data for the quipment of a unit to handle 25 or 30 tons of ore a day when the largest scale upon which the process had been tried so far had been about 25 or 30 pounds a day. I was unfortunately much pressed for time, under existing conditions, and had to attempt the impossible in getting a gas plant built, a furnace equipped, and tests completed within three months. It was found necessary to extend the time to be devoted to the tests; when this was arranged the gas plant was put in excellent shape, with washers and a fairly large gas holder, so that we we started up again, about the first of the year, we had good clean gas to use. During this second construction period we equipped a second MacDougal furnace with oil burners. Strangely enough, the totally unsatisfactory tests which we had made with oil burners in Brooklyn led us to believe that raw oil was not a suitable fuel for our purpose, and therefore the equipment of a furnace with oil burners was undertaken simply as a side show, so to speak. This furnace later proved more valuable to us and to our knowledge of the process than did the gas-fired furnace.

About the first of January we started up the gas-fired furnace, but unfortunately were unable to keep it operating for 24 hours at a stretch during the whole month—not because of any difficulty with the plant or process, but because storm after storm interrupted the power communication of the plant. These interruptions occurred on an average of twice a day for the first two weeks of January, and nearly once a day for the last two weeks. Meantime, however, our oil-fired furnace was made ready, and we seized one occasion when the shut-down was more prolonged than usual, to put it into operation, having hastily provided steam power for most of our requirements. The early part of February, therefore, we started to run the oil-fired furnace. Although still subjected to many interruptions, we gradually eliminated these, and as the weather became kinder to us, after a week or so we began to feel that we knew what to do.

The ore which we had to treat was crushed to ½ in. and as it was not in the slightest degree friable, and was very dense, ½-in. pieces were distinctly found to be too big. Therefore, a system of screen analysis was adopted on the calcines, and while our sulphur elimination from the material which passed the 10-mesh screen seemed to improve from day to day, nevertheless we found it extremely difficult to roast the ore down to the 5 per cent point which we aimed at under the conditions which we first imposed upon the furnace.

Careful analyses were made of the atmosphere existing on every hearth of this 18-ft. MacDougal furnace, and in the flue leading from it. For the first two weeks we devoted ourselves to tests in an atmosphere containing 1 per cent or less of free oxygen and rather generous percentage of CO; in other words, a highly reducing atmosphere throughout. Under these conditions we failed to get a better calcination than to about 11 or 12 per cent sulphur in the 10-mesh material. The larger pieces of ore, as they came from the furnace, were barely singed, and contained about 26 per cent sulphur, the original ore having averaged roughly 40 per cent. In all this period, hardly a trace of $SO_2$ existed in our escaping gases.

Time was again pressing and I found it impossible to try all the variations which I would have liked to try under these completely reducing conditions in the furnace. I therefore began slowly to allow a little oxidation to occur on the lower two hearths of the furnace, and while so doing we finally hit upon a set of conditions which seemed economically very important to the industry and to the problem of fume destruction. Let me state briefly what our best results were, maintained constantly for several days, and you will be able to judge whether or not we have reason to hope for important commercial developments in this process.

### Experimental Results

For about a week we fed at the rate of 24 tons in twenty-four hours. During this period the sulphur remaining in the 10-mesh calcines averaged 5½ per cent. The sulphur remaining in the total sample, of ½-in. material, coarse and fine together, averaged about 8.8 per cent. Oil consumption was 22 gal. per ton of ore, the oil being a very cheap material carrying 25 per cent of asphalt and of about 23 deg. Bé. gravity. The $SO_2$ in the fumes escaping from the furnace for the entire period was a trifle over 0.3 per cent. Labor required is practically the same as for ordinary MacDougal roasting, and, of course, the more furnaces and the larger tonnage treated, the lower the labor cost per ton, inasmuch as it takes just as many men to tend and feed one furnace as four. Please note that although the figures just given you are the averages of hundreds of samples of gas and calcines, the entire period showed improvement toward the end, and gave us an opportunity to study what changes in the furnace itself would conduce to still more favorable results. Our best results, maintained for twenty-four or forty-eight hours, towards the end of this period, may be stated briefly thus: Oil consumption 16 gal. to 17 gal. per ton of ore; 10-mesh calcines, 5.3 per cent sulphur (although for two or three days the calcines ran between 2.8 and 3.6 per cent sulphur); $SO_2$ frequently as low as 0.06 per cent, so low, in fact, that we got tired of titrating to an end point in a very weak iodine solution.

I trust you will all bear in mind that these tests were made in an existing furnace in which all mechanical arrangements, such as speed, angle of rabble blades, depth of the bed of ore, and length of time in the furnace, had all been fixed for conventional pyrites roasting operation, whence it is not surprising that some of these conditions demanded amendment to give the best results for quite a different operation. Such amendments, I am sorry to say, were beyond our possibilities in the short time at our disposal, and our metallurgical common sense must therefore come to our help in predetermining roughly what effect certain changes will have. I think that with 10-mesh ore, and with arrangements for more frequent rabbling, and for keeping the ore in certain portions of the furnace a greater length of time than the present conventional practice provides, we can maintain without difficulty the following results. In an 18-ft. MacDougal furnace I believe we can treat 40 tons of 10-mesh ore daily with 500 gal. of oil, roasting it down to 5 per cent of sulphur, and controlling the $SO_2$ fumes so that they shall never exceed 0.3 per cent, and probably average 0.15 per cent or less. You understand that these figures have not been attained, but that I am giving them simply as my opinion as to what can be attained in time.

Now for a word or two about the chemical reactions. In the upper portion of the furnace about one-half of the sulphur is distilled by heat alone. The very lowest portion of the furnace, say one-third of the hearth area, is devoted to the oxidation of iron, copper and remaining sulphur, by a free admission of air. In the middle third of the furnace a strongly reducing atmosphere and rather high temperature, say 1500 deg. F., are maintained, and it is in this central portion of the furnace that the $SO_2$ formed below is broken up and reduced to elemental sulphur. It is an undeniable fact that some $H_2S$ is formed in the upper regions, and it is equally undeniable that $H_2S$ will react upon $SO_2$ under certain conditions, forming water and sulphur, but I have not been able to prove that the $H_2S — SO_2$ reaction is the controlling feature in the reduction of $SO_2$. When a too heavily reducing atmosphere is permitted in the presence of liberated elemental sulphur and steam, certain undetermined organic sulphides are formed which seriously interfere with the production of sulphur. There seem to be two ways of preventing this interference: first, avoiding too great an excess of fuel; second, a quick drop in the atmosphere at the point where these excess oil vapors and free sulphur exist. Naturally, the former is the more economical way, but both have proved feasible.

### Methods of Sulphur Recovery

We provided a Feld washing machine to clean the elemental surphur from the gases, and for the first two or three hours after a free discharge of sulphur had been secured from the furnace, it looked as though this machine would take care of the sulphur most effectively; but, if my memory serves, four or five hours' creamy emulsion that came from the washer was led into tanks which had filter bottoms, the filtrate from which was beautifully clear and free from sulphur. Presently a disturbance appeared in the draft of the furnace, and investigation proved it to be caused by a complete clogging of all the gas passages in the washer. Fortunately we had provided facilities for by-passing the gases around the washer, and allowing them to escape from the stack into the air. This we did, and upon opening the washer found it completely clogged with yellow and gray sulphur, so sticky and plastic that neither a stream of water under high pressure nor a jet of steam would remove it from the interior surfaces.

Those who are familiar with the construction of a Feld washer will appreciate how impossible it was to clean the inaccessible spaces between the lead cones when once stuck up with this plastic mixture. After this first experience, we were able to use the washer for only an hour or so at a time, and then very ineffectively. Most of the time our gases, which consisted of a thick, heavy, yellow cloud of sulphur, were discharged through a fan to the stack and thence out into the atmosphere. Innocuous, it is true, but tantalizingly uneconomical.

To the small furnace in Brooklyn, we had previously attached a treater of the Cottrell precipitation type, and found that this electrolytic discharge was completely efficient in knocking down the sulphur. Unfortunately, business arrangements could not be made in the time at our disposal to install a Cottrell precipitation plant in connection with our MacDougal trials in California, so that until very recently I have been unable to say positively how well the liberated sulphur can be recovered. Our experience indicates that the current completely eliminated all solid sulphur from the gases, and I and most of my associates are reasonably sure that this method will prove both economical and efficient; it goes without saying that much experimentation will be required before satisfactory plant details can be worked out.

While looking into certain matters in Hungary about two months ago, I happened upon a Government sulphur factory which had been in operation for many years at a little place in Transylvania called Zalatna. I was interested to see with what facility the elemental sulphur was washed out of the gases in simple and inexpensive wooden towers containing many baffle boards over which a saturated solution of chloride of lime was flowing. The consumption of chloride of lime was almost nil; the emulsion coming from the foot of the towers was led into a series of tanks where the sulphur settled out quite completely without any filtering, and the clarified chloride of lime solution was again pumped to the top of the towers.

Naturally this suggestion seems a cheap way of solving our problem; I had three towers all half built in London, with the object of duplicating the performance which I witnessed in Hungary, when the war broke out and all business was stopped. Arrangements had about been perfected whereby I was to erect a plant in the northern part of Norway, similar to the one with which I experimented in California, but the war has also put a complete stop to that, so that our Hall process has had ill luck thus far.

In the discussion following Mr. Wierum's address, he gave the following information.

"The upper portion of the furnace is under a nearly continuous back pressure, that is, the upper two hearths. The third hearth has no pressure. The fourth, fifth and sixth hearths have a slight suction, increasing, of course, at the bottom. This suction amounts to about 4 mm of water. On the hearths where there is a suction we can use any of the ordinary types of oil burners, and rely upon an aspirating effect to draw in enough air to burn the oil; but on the upper hearths, where there is a back pressure, you cannot burn oil in any of the conventional burners. I got my idea of a burner for that condition from Mr. Peabody, who has invented a burner which is used in the United States navy. This burner relies upon the pressure of the oil to atomize it; the oil at 40 to 60 lb. pressure is led through a very tortuous passage, and is finally discharged through a very small hole. This little jet is in the middle of a 4-in. pipe, through which comes the supply of air for combustion, being delivered from a fan at a pressure of about 4 in., a very small pressure. The burner is very cleverly arranged so that the direction of the air is inward and the direction of the sprayed oil is outward, so that the two counteract one another and produce a distinctly local ignition of the oil. So far as I know, this is the only burner that will maintain any desired temperature against a back pressure, and in an atmosphere containing no oxygen."

* * * * * *

"The net result is that we have every reason to believe that it should be worth anybody's while to go ahead and finish these tests, at any reasonable cost, if he is interested in destroying sulphur fumes.

"I have always contended that it is a mistake to apply this process to any undertaking which requires close reckoning to figure out a profit. But at such operations as those in the Ural Mountains, or in Norway, or at Coram, at all of which places they have fairly cheap fuel and sulphur going to waste, with complaints about $SO_2$, there is no question in my mind that the salvage in sulphur would give you your roasting absolutely free, and eliminate the nuisance. But until we know that a profit can be made, and exactly how all details finally work out, I would not like to recommend anybody's installing it, for instance, in treating low-grade pyrites where the sulphur must be paid for in the first place.

"The cost of unpurified sulphur, with oil at 2.7 cents per gallon, figured out roughly at $4.75 per short ton; to that must be added about $3.50 for refining, because I do not believe that this sulphur is pure enough to sell to acid works."

---

## Chemical Resources of California

BY SAMUEL H. DOLBEAR

A good deal has been said and written in the last few weeks in answer to the question, "What is the American manufacturer to do now that his supply of European commodities has been cut off?" Unless this question can be solved quickly, many of our industries, some of which have already suffered, will be badly crippled.

In reading what has been offered by various writers in the technical journals, it has appeared to me that the importance of some of our own natural chemical resources has not been fully appreciated. In fact, mention of them, has in some cases been entirely omitted. I find, for example, the suggestion that some substitute will need be found for magnesite and that potash may be entirely eliminated for the present from fertilizing mixes.

Having made a rather careful study of the chemical mineral deposits of California, I take the liberty of offering a few facts concerning the more important of these in the hope that it may assist in some measure in the solution of the case before us. The United States Geological Survey has published much information of value to chemical manufacturers and users, and these publications may be obtained in most cases for the asking.

FIG. 1—MAGNESITE MINE AND CALCINING PLANT, FRESNO COUNTY, CALIFORNIA

*Magnesite.*—This material occurs abundantly in California and several deposits have been equipped with calcination plants; two or three are now producing and another is expected to resume operations within a few days. Prices have advanced sufficiently in this commodity to enable the producers to ship to the Atlantic seaboard since the European conflict arose, and with a market once created, it is believed that California magnesite may be handled profitably under normal conditions via the Panama Canal.

FIG. 2—CHROMIC IRON DEPOSIT, FRESNO COUNTY, CALIFORNIA

*Quicksilver.*—Importations of quicksilver vary remarkably as in 1906 only 84 lb. were brought into the United States, while in 1911 there was imported nearly 472,000 lb. according to the figures of the United States Geological Survey. California has many producing mines, the total production of which to date has been about 2,160,000 flasks of 75 lb. each. Of late years exports have dropped off rapidly from 13,534 flasks in 1905 to 310 flasks in 1910. It is apparent then that our own production finds a market at home and that we are dependent upon European producers for only about 25 per cent of our consumption.

The high prices recently prevailing have brought about much activity in this direction and it is not likely that the mines of California, Nevada, and Texas will experience any difficulty in supplying the demand.

*Chrome Ore.*—Chrome ore has been produced in California to the extent of about 40,000 tons. The largest production occurred prior to 1895, the decrease having been due to several causes, principal of which was the competition from New Caledonian and other deposits. Of late years the American production, which has come almost entirely from California, has been but a few hundred tons per year. With the stimulus of necessity, higher prices and lower freight rates through the canal, there is every reason to believe that activity in this material will result.

FIG. 3—PLANT OF CALIFORNIA TRONA COMPANY, SEARLES LAKE, CAL.

*Manganese Ore.*—There are numerous deposits of manganese in California and it is also found in Nevada and other Western States. Two of the California deposits are of easy access and one is within a freight rate of about $1 to seaboard. By exercising a little care in the mining and selection of this ore, a grade of 75 to 80 per cent $MnO_2$ may be maintained. Varying amounts of manganese ore have been shipped from California in the past years, the total production amounting to about 13,000 tons. It is entirely possible from a point of cost for California to supply such manganese ore as is used in the West and Central West in the ceramic arts, manufacture of dry and Leblanc cells, etc., under normal conditions. All that seems necessary to insure such production is new blood and sufficient capital to handle the industry.

*Ferro-Manganese.*—The Noble Electric Steel Company, at Heroult, Cal., is now equipping two of its furnaces, preparatory to producing this alloy. Others are also investigating the field with a view to its manufacture.

*Pumice.*—The volcanic regions of California are very extensive and large quantities of pumice are found in the State. On account of its abundance, it has found new fields, such as its use in concrete building construction. The resultant concrete is so much lighter than that in which crushed rock is used that a substantial saving in structural steel is effected. From the abrasive point of view, some of the California pumice is equal in quality to that of the Lapari Islands.

*Baryte.*—I do not know that the European war will result in any great shortage of this product as the American production is far in excess of its importations. Baryte is found in various parts of California and Nevada, and a series of experiments in the production of barium compounds has been carried on in a manufacturing plant near Oakland. It is stated that production on a considerable scale will be commenced shortly.

*Flint Pebbles.*—So far as I know, the entire Californian production of pebbles has been used heretofore within the State. Suitable shapes have been found and while the hardness is not quite that of the European variety, they have given very satisfactory service in cement mills. Most of them are a quartz rather than flint but are regarded as flint pebbles by the trade. What are undoubtedly large deposits have remained undeveloped. In a number of cases there are close to rail and readily accessible. I mention this subject as many of the American grinding plants depend on Belgium and other European countries for their pebbles.

*Mineral Colors.*—This is a rather indefinite term, and the deposits in California which may, for convenience, be classed as "mineral colors" include a great variety of minerals and a greater variety of colors. In Arizona and Nevada there are also occurrences of this character. Efforts have been made to operate only a few of such deposits, the ochres having found the largest market. A properly equipped plant, capable of receiving the crude ore and turning out a product satisfactory to the trade would, without question, greatly advance this industry.

*Alkalines.*—In this connection I desire to call attention principally to the potassium salts as the suggestion has been made that it would likely be necessary to eliminate potash from fertilizing preparations entirely for the present, with a mention of the possibility of obtaining some relief from the preparation of kelp and from alunite, felspar, etc.

At Searles Lake, in San Bernardino County, California, the discovery of potash in the alkaline deposit previously assumed to be chiefly valuable for its sodium carbonate content has attracted widespread attention. The available potash has been estimated at 30,000,000 tons. The United States Geological Survey and the Bureau of Soils originally laying claim to its discovery, were quite enthusiastic in the announcement of its discovery, but since it has been shown that the discovery of the presence of this important salt was the result of private investigation and was known some eight months prior to the departmental investigation, much space has been devoted to the possibility of finding undiscovered resources and the suggestion that it may be recovered from igneous and other rocks in which it is known to occur in an unsoluble state. A good description of this deposit may be found in the *Engineering and Mining Journal* of Feb. 1, 1913.*

*Conclusion.*—The items I have mentioned in the foregoing are but a few of the products which may be brought to account directly or indirectly in the present unusual conditions. The production of some of the salts of these elements, as is the case with magnesium chloride, is receiving serious consideration at this time. This latter is a source of great concern among those who require it, prices having advanced on the Pacific Coast from \$22.50 per ton to \$60 per ton. Experiments are being carried on along three different lines: (1) that of the direct manufacture of $MgCl_2$ from magnesite. (2) that involving the use of dolomite, and (3) through fractional crystallization of the bitter brines from the salt works, which brines are known to carry as high as 17.8 per cent $MgCl_2$ at 30 deg. Baumè. With the advent of local potash production, the manufacture of its chromium salts, as well as metallurgical chrome compounds may result.

With the development of the chemical industry in California, increased production from other of its mineral resources may be expected. If the war in Europe be long protracted, California may be expected to play a most important part in the solution of some of the problems now confronting the manufacturers of this country.

San Francisco, Cal.

# The Evaporator and the Power Problem in Electrochemical Plants*

BY OTTO MANTIUS

The electrolysis of sodium or potassium chloride solutions will produce liquors which with very few exceptions cannot be used or marketed without further concentration. In most cases considerable quantities of water have to be removed, and it is generally acknowledged that the cost for fuel, labor, repairs, interest and depreciation to be charged to the evaporating equipment have considerable influence on the rentability of the whole plant.

During the last few months we have heard a great deal about the conditions under which reciprocating engines, steam turbines or water power can be used for the generation of electric current to best advantage. In this paper I shall present some of the factors and conditions which should be considered when laying out an electrochemical plant where an evaporating system has to work in connection with water power or steam plant.

I shall not attempt to discuss the efficiency of the great variety of cells which are in daily use for the manufacture of caustic liquors, as the figures given below can readily be changed and discounted for any particular system. I shall not go into the question whether water, gas or steam should be used to produce the electric current. I shall restrict myself entirely to the discussion of those features and conditions which have a bearing on the design of the evaporating equipment.

The installation of an evaporator would be a very simple matter if we had to deal with sugar juice, black liquor or packing-house tank water. A double or triple effect for small quantities and a quadruple effect for larger amounts of liquor could be bought, installed and operated at comparatively low first cost and running expenses. The problem of a caustic liquor evaporator is somewhat complicated by the incrustations of the tubes, the corrosive action of the liquor itself and the high boiling point of the more concentrated solution, which practically eliminates the use of a quadruple effect even for large quantities, restricts the operation of a triple effect to certain favorable conditions, and makes a double effect the most economical equipment for a plant of medium capacity.

Inasmuch as this statement is quite contrary to ordinary practice, I give on p. 723 the figures for steam consumption of various equipments, which will explain and prove my contention.

My calculation has been based on the following assumptions:

---

*"Searles Lake Potash Deposit," by C. E. Dolbear

*A paper read at the Niagara Falls meeting of the American Electrochemical Society on October 3, 1914.

| | |
|---|---|
| Capacity in 24 hours | 20,000 lb. (9091 kg) NaOH. |
| Power required | 1500 electric horse-power. |
| Weak liquor | 20,000 gal. (75,750 liters) with 120 grams NaOH and 100 grams NaCl per liter. |
| Heavy liquor | 3440 gal. (13,200 liters) with 700 grams NaOH and 16 grams NaCl per liter. |
| Evaporation | 16,560 gal. (62,650 liters) in 20 hours = 828 gal. (3135 liters) per hour. |

The hourly steam consumption, including radiation loss, preheating of the weak liquor from 70° F. (21° C.) and evaporation of the wash water, will be as follows:

Single Effect—7900 lb.; 6000 lb. direct steam, 1900 lb. exhaust from pumps (3590; 2727 and 863 kg.).
Double Effect—5090 lb.; 3690 lb. direct steam, 1400 lb. exhaust from pumps (2312; 1676 and 636 kg.).
Triple Effect—4600 lb.; 3400 lb. direct steam, 1200 lb. exhaust from pumps (2090; 1544 and 546 kg.).
Triple Effect and Single Effect—4300 lb.; 3000 lb. direct steam 1300 lb. exhaust from pumps (1952; 1362 and 590 kg.).

Single effect and double effect are to be operated with steam at 7-lb. and 20-lb. gauge pressure (0.5 and 1.3 kg. per sq. cm.), triple effect at from 60 lb. to 70 lb. (4 to 4.7 kg. per sq. cm.) and the combination triple effect and single effect with steam at from 7 lb. to 20 lb. (0.5 to 1.3 kg. per sq. cm.). In the latter arrangement the triple effect concentrates the weak liquor to about 400 grams per liter, and the single effect finishes the process to 700 grams NaOH per liter. This arrangement will permit the use of low-pressure steam, and should always be used where larger quantities of liquor have to be handled.

The above figures show that the efficiency of the evaporator increases with the number of effects as usual, even if the difference is not as large as might be expected from general practice. The comparatively high steam consumption of the high pressure straight triple effect is due to the increased radiation losses and the large amount of wash waters to be handled and preheating to be done.

These conditions will change as soon as we use a part or all of the exhaust steam of engines or turbines for the evaporation of the caustic liquors.

Where the electricity for the cells has to be generated in a steam plant, either steam turbines or reciprocating engines may be used and the exhaust utilized in the evaporator. As the quantity of steam required for power purposes is about three times larger than the amount needed for the evaporator, the ordinary method of using all the engine exhaust at about 5 lb. (0.3 kg. per sq. cm.) pressure for the concentration of the caustic liquor can only be applied in very small plants by running the evaporator about 7 hours per day and operating the engine during the rest of the time in connection with the condenser attached to the evaporator.

In most cases it is necessary to run a multiple effect evaporator continuously and utilize only a part of the steam, which has entered the engine or turbine at high pressure and is withdrawn at from 20 lb. to 30 lb. (1.3 to 2.0 kg. per sq. cm.). I find that for this kind of work steam turbines are not quite as suitable as reciprocating compound engines, as in a steam turbine a large part of the work is done during the low pressure period. While actual tests on small compound engines show that 10 lb. (4.5 kg.) steam withdrawn from the receiver at 20 lb. (9.1 kg. per sq. cm.) pressure require only from 5 lb. to 6 lb. (2.25 to 2.75 kg.) extra steam at 125 lb. (8.3 kg. per sq. cm.) pressure, the guarantees given for large steam turbines ask for 8 lb. (3.6 kg.) extra steam at 150 lb. (10 kg. per sq. cm.) pressure added for 10 lb. (4.5 kg.) steam withdrawn at 20 lb. (1.3 kg. per sq. cm.) pressure.

To produce 20,000 lb. (9091 kg.) NaOH in 24 hours the steam plant should develop 1500 electric horsepower. A compound condensing Corliss engine will use 15 lb. (6.8 kg.) steam per electric horsepower per hour and increase its steam consumption 1 lb. (0.45 kg.) for every 2 lb. 0.91 kg.) discharged from the receiver at 20 lb. (9.1 kg.) pressure or higher.

Assuming that 1 ton of coal furnishes 15,000 lb. (6820 kg.) of dry steam at a cost of $3, i.e., 1000 lb. (454 kg.) of steam for $0.20, the steam and coal consumption of engine and evaporator combined will then be as follows:

*Single Effect.*

| | | |
|---|---|---|
| Engine | 1500 × 15 × 24 = | 540,000 lb. (245,300 kg) steam |
| Evaporator | 3000 × 20 = | 60,000 lb. ( 27,270 kg) steam |
| Pumps | 1900 × 20 = | 38,000 lb. ( 17,270 kg) steam |
| | | 638,000 lb. (289,840 kg) steam |

Fuel cost per day = $127.60; per 1000 lb. (454 kg) NaOH = $6.38.

*Double Effect.*

| | | |
|---|---|---|
| Engine | 1500 × 15 × 24 = | 540,000 lb. (245,300 kg) steam |
| Evaporator | 1845 × 20 = | 36,900 lb. ( 16,760 kg) steam |
| Pumps | 1400 × 20 = | 28,000 lb. ( 13,330 kg) steam |
| | | 604,900 lb. (275,390 kg) steam |

Fuel cost per day = $120.98; per 1000 lb. (454 kg) NaOH = $6.05.

*Triple Effect and Single Effect.*

| | | |
|---|---|---|
| Engine | 1500 × 15 × 24 = | 540,000 lb. (245,300 kg) steam |
| Evaporator | 1500 × 20 = | 30,000 lb. ( 13,635 kg) steam |
| Pumps | 1300 × 20 = | 26,000 lb. ( 11,820 kg) steam |
| | | 596,000 lb. (270,755 kg) steam |

Fuel cost per day = $119.20; per 1000 lb. (454 kg) NaOH = $5.96.

A straight triple effect naturally cannot be operated on steam of 20 lb. (1.3 kg. per sq. cm.) pressure, and live steam has to be used altogether.

*Triple Effect.*

| | | |
|---|---|---|
| Engine | 1500 × 15 × 24 = | 540,000 lb. (245,300 kg) steam |
| Evaporator | 3400 × 20 = | 68,000 lb. ( 30,900 kg) steam |
| Pumps | 1200 × 20 = | 24,000 lb. ( 10,900 kg) steam |
| | | 632,000 lb. (287,100 kg) steam |

Fuel cost per day = $126.40; per 1000 lb. (454 kg) NaOH = $6.32.

In all cases evaporators and pumps work only 20 hours per day, while the cells are naturally operated during the full 24 hours.

These figures show that for a production of 3600 tons caustic per year the cost of fuel is about $2,000 higher for a straight triple effect than for a double effect or combination triple and single effect. Besides, we must not forget that a high-pressure triple effect is considerably more expensive in first cost and repairs, and is sometimes difficult and even dangerous to operate. Wherever possible, evaporators for caustic liquors of high density should be operated under vacuum, as it will prevent loss of caustic and reduce the corrosive action of the liquor.

Quite a number of electrochemical plants obtain the necessary power at very low rates from central power plants, but have to install boilers to furnish steam for the evaporators. At first glance it would appear that a high-pressure triple effect might be the most economical equipment, but the following figures will prove that as far as cost of power is concerned a different arrangement is preferable. Let us assume that only $22 is charged for 1 electric horse-power per year and that 1000 lb. (454 kg.) steam cost $0.20 as before.

*Straight Triple Effect.*

| | | |
|---|---|---|
| Cost of energy | $\frac{1500 \times 22}{365} =$ | $90.40 |
| Evaporator and pumps | 4600 × 20 = 92,000 lb. = | 18.40 |
| | | $108.80 |

Therefore 1000 lb. (454 kg) NaOH = $5.44.

We have seen before that a combination triple and single effect can be operated at low pressure and uses less steam than a stright triple effect. We can, therefore, first use the high-pressure steam in a special compound engine to furnish a certain amount of power at not any cost for fuel, and then utilize the exhaust for the evaporation of the liquor. Assuming that the engine will use 23 lb. (10.5 kg.) per hour per electric horsepower, and therefore produce 130 electric horsepower from the available 3000 lb. (1364 kg.), we have only to purchase 1370 electric horsepower, outside power, and the cost will be as follows:

*Combination Triple and Single Effect.*

| | | |
|---|---|---|
| Energy | $\frac{1370 \times 22}{365} =$ | $82.60 |
| Engine and evaporator | $130 \times 23 \times 24 = 72{,}000 =$ | 14.40 |
| Pumps | $1300 \times 20 = 26{,}000 =$ | 5.20 |
| | | $102.20 |

1000 lb. (454 kg) NaOH = $5.11.

This would mean a saving of over $2,400 per year, less interest, depreciation and repairs of engine. Quite frequently it might not be desirable to install such an engine, but there will always be a number of pumps and small engines the exhaust of which should be used in the evaporating equipment.

We could even go a step further and in stall a 500-hp. compound condensing engine, use in the evaporator steam taken from the receiver and contract for only 1000 hp. to be taken from the central station. Considering the cost of extra labor, repairs and depreciation, we would not save much, but the engine could be arranged so as to take up the peak load, for which otherwise in most cases heavy penalties have to be paid, and the plant could be operated at two-thirds of its normal capacity by shutting down the engine without having to pay for more than the 1000 hp. Besides, the plant has not to be closed down entirely in case the central plant should not be able to furnish the current.

Similar conditions prevail in plants where gas engines or heavy oil engines are used to generate the current for the cells. A double effect or combination triple and single effect using exhaust steam from auxiliary engines and pumps will give the best results.

A type of engine used very little in this country is the Lentz patented superheated steam engine, which even in small units will produce current at surprisingly low cost. I was told last year during a visit to Germany that 1 electric horsepower hour can be produced by 10 lb. (4.5 kg.) of steam and less in a 300-kw. unit. This would make the Lentz engine the ideal motive power for small plants furnishing bleach liquor and caustic for paper mills.

The foregoing figures lead to the conclusion that a straight triple effect operated with high-pressure steam should never be used for the concentration of caustic liquors. The first cost is high, and the expenses for fuel, repairs and renewal are more than for any other arrangement. Besides, such a triple effect is considered by many people a general nuisance and source of trouble on account of the difficulties in keeping joints and valves tight.

As far as the cost of fuel per 1000 lb. (454 kg.) NaOH is concerned, there is not much difference between a single, double or combination triple and single effect, but low first cost and simplicity of operation should induce us to choose a single or double effect for small capacities up to 5 tons NaOH per day; for larger plants, and especially where the cost of coal is high, and large amounts of cooling water can be had at only considerable expense, a double effect or combination triple and single effect should be installed. The proper arrangement has to be determined for each plant, and no general rules can be given.

I wish to add a few words concerning the general design of the evaporating equipment:

1. For small single effects operating only 10 hours per day no reserve is needed, as all repairs can be done over night. The piping of multiple effects running continually should always be arranged so that any pan can be cut off entirely for repairs.

2. Steel, charcoal iron or nickel steel tubes should be used only up to 40° Bé., as the corrosive action of caustic up to this density is very small, and any kind of tube will last a long time, unless the liquor contains a considerable amount of corrosive impurities.

3. For the concentration from 40° to 50° Bé. and higher, only special cast-iron tubes should be used, because cast iron is the only material that will withstand the action of the hot concentrated caustic liquor. In Germany almost all the caustic liquor above 40° Bé. is handled in cast-iron evaporators. The first cost of such an equipment is somewhat higher, but this difference is soon paid for by the saving in repairs and the increased efficiency of the plant, as there is no time lost in shutting down to replace worn-out tubes. Some of the largest manufacturers of caustic in this country prefer to use copper tubes almost exclusively, as copper will wear longer and more uniform than steel or charcoal iron. Besides, the scrap value of the discarded tubes is quite high. On the other hand, the first cost is considerable, and where large amounts of salt have to be handled the copper tube disappears quickly on account of the mechanical abrasion caused by the salt passing along the copper surface at high speed.

It was not my intention to consider all possible combinations between evaporator and the source of power, as this is not the time and the place to make such an exhaustive investigation. I only wished to point out the economic and practical disadvantage of a high-pressure straight triple effect when handling caustic liquor up to 50° Bé., and the good results that may be obtained from a compound or triplex condensing engine when working in connection with a double effect evaporator or a combination of low-pressure triple effect and single effect with a cast-iron heating surface.

Buffalo, N. Y.

## Electro-Chemistry and Metallurgy in Great Britain

*(From Our Special Correspondent.)*

### The Institute of Metals

The meeting of the Institute of Metals announced to be held at Portsmouth on the 10th and 11th of September did not take place on account of the war. But the papers which would have been read and discussed were formally presented at a meeting in London on the 10th and discussion was invited by correspondence in the Journal of the Institute.

### The Influence of Coke on Corrosion

In their second report to the corrosion committee of the Institute of Metals, Dr. G. H. Bengough and Mr. Jones gave out, as the result of their researches, that coke exerted no deleterious action when in contact with immersed Admiralty brass, and generally had rather a beneficial effect.

Mr. Arnold Philip, in a convincing paper, flatly contradicted the statements so made, which he regarded as an entirely erroneous departure from the generally accepted views on the theory of corrosion. The report in question stated, in effect, that coke in close contact with condenser tubes of Admiralty brass, whether in stagnant or running sea-water at ordinary temperatures, had no material influence on the amount of corrosion, either local or general, and did not cause dezincitification, buti n general had a slight retarding effect on the speed of corrosion.

The author asserted most positively that coke in contact with condenser tubes in sea-water caused an acceleration of corrosion which was a very real and important source of trouble, and this was a fact which had been known for many years to all engineers who had to deal with corrosion, particularly in connection with condenser tubes, and had long ago attained the status of a truism. He had made many dozens of experiments with pieces of Admiralty brass condenser tubes to which fragments of coke were tied with cotton, and immersion in either stagnant or running ordinary sea-water at temperatures varying from atmospheric up to 50 deg. C., proved that in every case an acceleration of corrosion was caused by the coke, while an appearance of dezincification was produced in two days at ordinary temperatures.

### Depositing Metallic Coatings by Spraying

A paper by Mr. R. K. Morcom described an effective method of uniformly depositing metallic coatings by spraying heated metal by means of high-pressure air or gases. The apparatus is the subject of British patent No. 2801 of 1912, and consists essentially of two concentric nozzles with a central carrier for a wire of the metal to be deposited.

The inner, or melting, jet focusses a flame of oxy-hydogen or other gaseous fuel on the wire at a short distance from the nozzle, while the outer or spraying jet delivers air or other suitable gas at a pressure of 80 lb. per square inch, which carries away a stream of minute particles of the heated metal and deposits them on the object to be coated and also serves to keep the nozzles and object cool.

It is stated that the hand can be held in the jet without inconvenience and be coated with metal. The consumption of air is from 45 to 50 cu. ft. per minute, and the most economical rate of supply of gases for the melting jet is about 1.5 cu. ft. of hydrogen and 0.5 cu. ft. of oxygen, or about 0.8 cu. ft. of coal gas with 0.65 cu. ft. of oxygen per minute.

The manipulation of the apparatus can be varied to produce either porous or non-porous coatings, and, with certain metals, any deposit from pure metal to pure oxide. Fusible non-metallic substances can also be sprayed, and alloy deposits may be obtained from stranded wires.

### The War and Engineering Trades

An order of considerable magnitude for the machinery and steel work for the construction of dock gates, caisson and swing bridges at the new extension of the Royal Albert Docks was, before war was in sight, placed in Germany by the Port of London Authority. The carrying out of the contract in that country being now out of question, it has now been given to Sir Wm. Arrol & Company, of Glasgow.

The trade of Sheffield has already undergone marked improvement, and continued expansion is practically certain to follow. The bayonet works are naturally very active; a valuable order for shoes and dies for Freemantle, which would in the ordinary course have gone to Germany, has been received, and fairly heavy contracts for steel work for Japan represent new business.

At Birmingham the small arms and ammunition factories are working day and night; good orders for locomotives and rolling stock have been transferred from German firms to British engineers, and a considerable share of the work has come to the district, while orders from the War Office for light constructional steel work, corrugated sheets, barbed wire, tubes and pumps are keeping many works very busy.

In the Tyne district firms doing Admiralty work are keeping their shops going continuously—day and night and Sundays—to cope with the demands for war material, and there is considerable difficulty in obtaining an adequate amount of skilled labor.

### Market Prices

*September*, 1914

Prices not official

| | £. | s. | d. | | £ | s | d |
|---|---|---|---|---|---|---|---|
| Aluminium ingots, ton lots | | | | | 83 | 0 | 0 |
| Alum lump, loose, per ton | 5 | 5 | 0 | to | 5 | 10 | 0 |
| Antimony, black sulphide powder, ton | | | | | 25 | 0 | 0 |
| Borax, British ref. crystal, cwt | | 18 | 6 | to | | 19 | 6 |
| Copper sulphate, ton | 17 | 10 | 0 | to | 18 | 10 | 0 |
| Copper ore, 10% to 25% unit | | | | | | | |
| Caustic soda, 70%, cwt | | 9 | 9 | to | | 10 | 3 |
| Ebonite rod, lb. | | | | | | 3 | 6 |
| Hydrochloric acid, cwt | | | | | | | |
| India rubber, Para, fine, lb | | | | | | 2 | 10 |
| Mica in original cases, medium | | 3 | 0 | to | | 5 | 0 |
| Petroleum, Russian spot, gal | | | | | | | 9¼ |
| Quicksilver, Spanish, bottle | | | | | 7 | 17 | 0 |
| Sal ammoniac, cwt. | | 40 | 0 | to | 2 | 2 | 0 |
| Sulphate of ammonia, ton | | | | | 10 | -- | 0 |
| Sulphur, recovered, ton | | | | | | | |
| Shellac, cwt. | | | | | 3 | 2 | 6 |
| Platinum, oz., nominal | | | | | 9 | 5 | 0 |
| Tin ore, 70%, ton | | | | | | | |
| Zinc sheets, scarce | 42 | 10 | 0 | to | 45 | 0 | 0 |

The Metal Exchange remains closed.

*Tin.*—General depression was somewhat relieved towards the middle of the month by Continental demand through absence of German supplies, Standard being quoted about mid-month at £134 to £136 on minimum quantities.

*Copper.*—In copper the exchange remained closed. At the beginning of the month, owing to restricted selling consequent on this, copper changed hands as low as £52. Best selected was officially fixed at £57.10.0 to £58.10.0 (11th).

*Scotch Pig.*—Market very quiet. Settlement price 57/—.

*Haematite.*—Settlement 66/—.

*Cleveland.*—At mid-month 52/11, but has since declined considerably, being quoted later at 50/11½.

*Lead.*—The market is quiet. English lead is fairly steady at £19.15.0 to £20.0.0.

## Recent Chemical and Metallurgical Patents

### Fixation of Atmospheric Nitrogen

**A New Nitride Process.**—Among the various processes for the fixation of atmospheric nitrogen one particular class which has attracted considerable attention in recent years is characterized by, first, the production of a metallic nitride by reaction of the metal with atmospheric nitrogen; second, by production of ammonia from the nitride, and third, the regeneration of the metal, so that with respect to the metal the process is cyclic. Perhaps the first suggestion in this line was to use lithium (this journal, April, 1906, p. 122). The lithium nitride, formed by the reaction $3 Li + N = Li_3N$, is treated with water, yielding ammonia and lithium hydroxide, and the latter is electrolyzed for the regeneration of metallic lithium. This was considered too complicated and expensive. One special process which has furthest advanced on this principle is the Serpek process in which aluminum nitride is produced from bauxite and nitrogen, followed by decomposition of the nitride by water or caustic soda solution, thereby liberating the nitrogen as ammonia and producing alkaline aluminate solution from which pure alumina can be obtained (this journal, Vol. X., p. 745, Vol. XI., pp. 137, 139, 281).

Two patents just granted to Prof. JOHN E. BUCHER of Brown University, Providence, R. I., describe a new process which in its general principle belongs to the class above described. Its distinctive feature is that the nitride is not decomposed by water or caustic soda solution, as above, but by a mineral acid, or by some other hydrogen compound such as the acid salts, ammonium salts, etc. In the patents examples are given for the following acids, acid salts, etc.: $HCl$, $NaHCO_3$, $NH_4CL$, $NH_4Br$, $NH_4I$, etc. The advantage claimed by the inventor over the use of water or caustic soda solution for treatment of the nitride is stated as follows: "A characteristic property of nitrides of the metals and metalloids—lithium, magnesium, calcium, barium, strontium, aluminum, silicon, etc., and of boron nitrid —is their power to decompose water at the ordinary, or at more or less elevated temperatures, as the case may be, to form gaseous ammonia, and a hydroxide or oxide of the metal or metalloid. This method of producing ammonia is not economical because the oxide or hydroxide remaining has little value as such, and must be reduced to the metallic state before it can absorb nitrogen to reform the nitrid, and it is very much more difficult and expensive to reduce the oxides and hydroxides of the nitride forming metals than to reduce the haloids of said metals.

The principle of the Bucher process is shown in the most simple way in the following example:

$$3\,Ca + 2\,N \text{ (from air)} = Ca_3N_2.$$
$$Ca_3N_2 + 6\,HCl = 2\,NH_3 + 3\,CaCl_2.$$

"Electrolysis of the so produced chloride of calcium gives chlorine and calcium, and the former may be utilized as such, or may be used to form hydrochloric acid, while the calcium may be converted into calcium nitride to be reacted upon by hydrochloric acid. My process is hence adapted to any industry wherein hydrochloric acid is available or wherein it may be produced."

As adapted to the ammonia-soda industry, the process is described as follows: "Many attempts have been made to utilize the chlorine of common salt, used in the ammonia-soda process, for producing bi-carbonate and carbonate of soda. Solvay and Mond made many experiments with this end in view, but up to the present time none have proven economically successful. The common practice of to-day allows all of the undecomposed common salt, which amounts to about 30 per cent of the total quantity used, and much of the chlorine of the decomposed salt to go to waste, some of the chlorine combined with calcium being recovered and utilized as calcium chlorine. My invention renders possible the saving and utilization of all of the undecomposed common salt, and substantially all of the chlorine of the salt which becomes decomposed, while furthermore resulting in an increase of approximately one-third of the quantity of ammonia present in the cycle.

"The manner of conducting my process in connection with the ammonia-soda industry is as follows: The mother liquor from the crude bi-carbonate of soda produced in the carbonating tower is evaporated to dryness in any suitable evaporator; and the free or volatile ammonia is collected by brine in the usual manner; a residue consisting essentially of a mixture of dry ammonium chloride and sodium chloride being obtained. This mixture is then heated to the subliming point of ammonium chloride, to wit, about 300° C., and the ammonium chloride is condensed to a solid sublimate leaving the sodium chloride behind in an especially pure condition, suitable for any use, such as table salt, or for strengthening the brine used in the ammonia-soda process; while all of the ammonia corresponding to the decomposed sodium chloride is thus recovered in the form of dry ammonium chloride. The ammonium chloride is then brought into contact with a nitride at the proper temperature, usually a dull red heat. Many nitrides are capable of reacting with ammonium chloride, in practically all cases with evolution of heat, producing ammonia or ammonium chloride and a chloride of the metallic base of the nitride. For example, calcium nitride reacts, in this connection, as follows: $Ca_3N_2 + 6\,NH_4Cl = 8\,NH_3 + 3\,CaCl_2$.

"The reaction in this case evolves sufficient heat to maintain itself after it has once been started, and if moisture be excluded, which is preferable, the reaction takes place quantitatively and anhydrous ammonia and anhydrous calcium chloride are produced. The ammonia needs only to be cooled and compressed, either by the pressure produced in the generator, or by mechanical compression, to immediately liquefy it. The calcium chloride hereby produced is well suited to serve as an electrolyte in an electric furnace, and is preferably so used in the electrolytic step of the process leading to the re-formation of calcium nitride." Various reactions are also mentioned in which magnesium is the metal in the cyclic process instead of calcium.

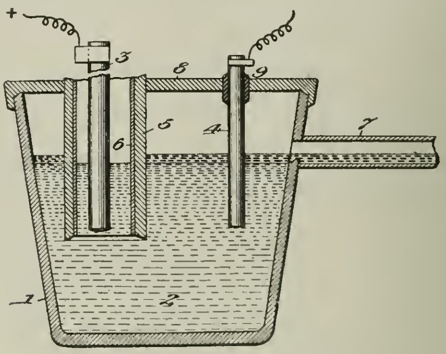

FIG. 1—ELECTROLYTIC FURNACE

The electrolytic process is carried out as follows: In Fig. 1, the iron pot 1 contains the fused salt 2, while 3 is the anode and 4 the cathode. Chlorine is set free at 3, collects within the tube 5 and is carried off. The metal (calcium, magnesium, sodium, etc) is set free at 4 and carried off through tube 7 and is then "introduced into the reaction tube 10, Fig. 2, which latter may be heated in any suitable manner, as by a number of Bunsen burners 11. The sodium 12, for example, in the retort or reaction tube is converted to a nitride by passing nitrogen or a suitable nitrogenous reagent, e.g., free nitrogen, through the tube, such reagent passing thereinto from a tube or pipe 13, and the unused portion of the same escaping via tube 14. Cocks or valves 15 may be provided in these last-mentioned pipes. The halogen, e.g., chlorine, escaping from pipe 5, is collected and may be combined with hydrogen, for example, to form hydrochloric acid; and when the nitride of magnesium, for instance, in tube 10, is reacted upon with said acid, which may be introduced into said tube in any suitable manner, as by injection * * * ammonia formed may escape through tube 14, while the resulting reformed haloid salt will remain in the reaction tube, from which it may be afterward removed preparatory to again electrolyzing the same." (Patents 1,113,598 and 1,113,599, October 13, 1914.)

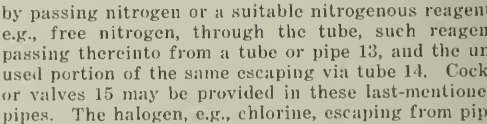

FIG. 2—REACTION TUBE FOR PRODUCTION OF NITRIDE

**Absorption of Nitrous Vapors in the Dry and with Heat by the Aid of Lime.**—A patent of Alphonse Theophile Schloesing, Paris, France, applies to a process by which a better heat-regeneration is obtained in the fixation of atmospheric nitrogen. Air is dried with sulphuric acid before entering the electric heating furnace (in which discharges are passed through the air) and leaving the same the air contains nitrous vapor. It then passes into a heat-exchanger, where part of its sensible heat is given off to the gases escaping from the absorber, freed from nitrous vapor. These re-heated gases can now be used to dry and dehydrate the lime used for the absorption of those nitrous gases in the absorber. The gases which gave off part of their heat are still further cooled down to about 300 or 400 deg. C. and enter now the absorber, where their nitrous content is retained. Leaving this absorber still hot enough, part of it may be used to concentrate the sulphuric acid for air-drying, whereas the other part is re-heated in the heat-exchanger as set forth above. No external heating is required throughout this process. (1,092,295, April 7, 1914.)

### Metallurgical Furnaces.

**Melting Furnace.**—A combined reverberatory and stack furnace is described by GRENVILLE MELLEN, of East Orange, N. J. The flame passes over an inclined hearth and through an arch into the shaft, where it preheats the charge. The molten metal accumulates in a sump, where it is separated from any lumps by a refractory shield. The product can be further treated in a refining chamber, which is protected from radiation by a cover. Finally it flows into a pot in front of the furnace. (1,092,938, April 14, 1914.)

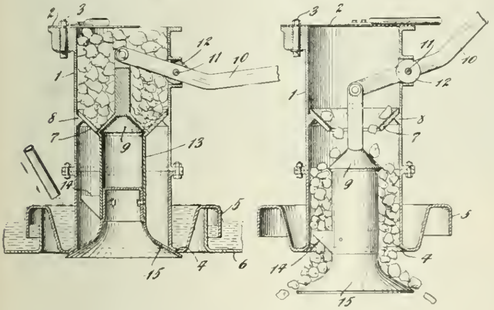

FIG. 3—HOPPER FOR GAS PRODUCER

**Hopper for Gas-Producers.**—To evenly distribute fuel in a producer, WM. A. JONES, of West New Brighton, Staten Island, N. Y., has devised the hopper shown in the two diagrams of Fig. 3. It consists of an upper loose ring 7, closed by the valve 9 extending cylindrically below and ending in a flared spreader-plate, fitting tightly to a seat 4, on account of the looseness of ring 7. Three guides for the bell are also provided. The distance with which the coal will fall from the producer-center will depend upon the height of its fall, the angularity of the spreader plate and finally also on the height above the coal surface. (1,090,857, March 24, 1914.)

**Reversing Valve.**—A reversing valve, in which the use of cooling water is almost avoided and the walls are brick-lined and cooled by air is patented by JEROME R. GEORGE, of Worcester, Mass. The valve itself is divided into sections, one of which is closed by a cover being lined and connecting two gas flues of the heating furnace. The open segmental section is for admission and regulation of air, its two connecting walls between the circular wall-ends and the skew-back, being curved. Air pockets are provided between lining and shell, to cool the former. Only skew-back and pan receive cooling water. (1,093,047, April 14, 1914.)

### Electric Furnaces.

**Electric Melting Furnace for Medium Temperatures.**—ERNESTO STASSANO, of Turin, Italy, and NAPOLEON PETINOT, of Niagara Falls, N. Y., have obtained a patent on an electric melting furnace for copper, alloys, etc., the furnace being of the radiation type. The furnace has already been described in our October issue, page 645. The main features are the eccentricity of the furnace shell and melting chamber, the axis of the latter being above the other. On account of this thicker refractory filling the bath is well protected against heat losses, whereas the highly heated but thinner roof allows a better cooling. A charging device, consisting of a turning-disk with a funnel, a hopper closed on top, permit charging without admitting air to the furnace. The electrodes are inclosed in a cylinder and held by a hollow water-cooled rod, sliding on guides and moved by means of hydraulic pressure. (1,093,494, April 14, 1914.)

**Calcination of Granular Carbon and Production of Graphite.**—A continuous electric furnace for the production of granular graphite is patented by JOHN W. BROWN, of Lakewood, O. (National Carbon Company). The vertical and polygonal type contains an outer and an inner cylindrical wall, with a cover on top, through which the upper carbon electrode reaches into the furnace. The three lower horizontal electrodes pass through sleeves in the inner and outer walls and cannot with a cylindrical carbon channel, at the bottom of which a conveyor removes the granulated product. The charge, fed into the hopper, is carried upwards by a hoist between the two cylindrical walls and absorbs thereby heat from the hot product inside. The charge is tilted on top, passes the intense hot zone and falls into the carbon channel where it gives heat off to the fresh charge. A vertical modification and two horizintal designs are further described. (1,093,382, April 14, 1914.)

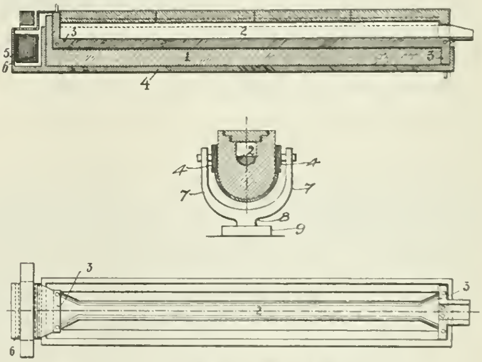

FIG. 4—INDUCTION FURNACE

**Electric Induction Furnace.**—ALOIS HELFENSTEIN, Vienna, Austria, uses the casing of a long-shaped furnace as conductor for the secondary current to the bath. This casing surrounds the furnace concentrically effecting thereby a natural cooling. Fig. 4 shows a vertical longitudinal section, a vertical cross-section, and a plan of the furnace. 1 indicates an extended furnace tube in which the metal 2 to be heated by the current is contained. At the ends of the tube water-cooled poles 3 are arranged, which transmit the induced secondary current on the one hand from the secondary winding 6, and on the other hand through the furnace-casing 4 to the metal bath 2. The primary winding of the transformer is shown at 5. (1,093,328, April 14, 1914.)

**Moving-Electrode Furnace.**—Instead of fixed electrodes, HENRY H. BUCKMAN, Indianapolis, Ind., uses rotating eletcrodes to obtain a better and quicker distribution of heat in an electric furnace. Three electrodes are being carried by a support, fastened to a vertical rotating member. These arms and the member are water-cooled and the electrodes isolated from the support, one conductor leading direct to the middle electrode, while the other divides and supplies the two outer ones. All three electrodes rotate eccentrically with different distances from the center to cover as much surface as possible of the bath, the current passing through and from the middle to the two outer electrodes. The distance of these outer electrodes from the center electrode is kept equal. (1,092,764, April 7, 1914.)

**Electrode Construction.**—According to a patent of JOHN W. BROWN, of the National Carbon Company, electrodes can be built up of segments and keyed together by means of ribs and complimentary grooves, both being shunted to insure a wedging action of all the parts. The electrodes are best started with varying lengths, the ends of each being leveled to force them into better contact. The center may be made hollow. (1,091,559, March 31, 1914.)

### Iron and Steel

**Refining Pig Iron.**—Pig iron can be improved so as to be equal to cold blast-iron, according to a patent of VICTOR STOBIE, Sheffield, England. The liquid metal from the blast-furnace is treated in an electric-furnace under a refining-slag of about 60 per cent lime and 40 per cent silica and kept free from iron oxide by additional carbon or deoxidizer. The bath is stirred up by throwing limestone into it, the carbonic acid causing violent evolution. After this the bath is allowed to rest. Too much limestone would reduce silicon, manganese and phosphorus. (1,093,892, April 21, 1914.)

**Direct Production of Iron and Steel in a High-Pressure Furnace.**—CARL OTTO, Dresden, Germany, describes a somewhat complicated method of producing iron or steel in a furnace under pressure. Spongy iron is first produced by carbon monoxide in a clay vessel heated from the outside by producer-gas. At the bottom is a charge of pure iron or steel, on top of it is charcoal mixed with ore, and on top of this a fuel chamber is provided, containing inferior fuel with an electric resistance imbedded herein. The vessel with the charge is heated and the $CO_2$ from the reduction zone passes up and into the electrically heated fuel chamber. The CO so produced is used partly for burning and the other part takes the place of the $CO_2$ in the ore-chamber for further reduction. Gas-circulation is produced by a blower. A second electric resistance is provided at the base of the vessel to form and maintain a sump of mother metal, which bath under pressure also absorbs CO, so removing all remaining protoxides. (1,089,951, March 10, 1914.)

**Use of Peat in Production of Sponge-Iron.**—Objections to the use of peat as fuel in iron reduction reside in its tendency to disintegrate in the shaft furnace and its inability to sustain the burden of the charge. It is proposed, however, by PER ANDERSON, of Arvika, and ERIK EDSON ODELSTIERNA, of Stocksund, Sweden, to make use of this fuel in a metallizing or sponge-iron process, by thoroughly mixing the powdered peat with iron ore, charging the mixture in a receptacle and heating the latter externally by combustion of gas. The reduction thus takes place while the ore and metal are still in a solid state. (1,105,870, Aug. 4, 1914.)

### Gold and Silver

**Treatment of Anode Residue.**—Anode residues from the electrolysis of copper bullion contain gold, silver and some copper. The recovery of the copper and the preparation of the precious metals for subsequent refining and separation, are objects of a process patented by Dr. EDWARD KELLER, of Perth Amboy, N. J. The anode residues are first filter-pressed and then treated with concentrated commercial sulphuric acid in just sufficient quantity to dissolve the copper present or render it soluble. After this treatment the copper can be dissolved in hot water, and the decopperized precious-metal residue refined for the formation of Doré bars. For residues from crude converter copper, the following mixture is made: 2000 lb. residue (41.2 per cent copper) and 2760 lb. sulphuric acid at 66° Baume, or 67 lb. of acid per unit (20 lb.) of copper. For residues from refined copper: 2000 lb. residue (15.1 per cent copper) and 460 lb. acid at 66° Baume, or 30.7 lb. acid per unit of copper. The mixture is heated at a temperature of about 450° F. and subsequently dissolved in hot water, whereby from 95 to 99 per cent of the copper is recovered in a neutral solution suitable for return to the electrolytic tanks. (1,110,493, Sept. 15, 1914.)

### Copper and Zinc

**Improvement in Bessemerizing Copper Matte.**—In the usual method of recovering copper from matte the latter is blown in a converter with the addition of silicious flux, with the result that there is first formed a slag of silica and iron which is skimmed, after which the blow continues to reduce white metal, or sulphide of copper, to the metal. The copper is subsequently treated in a reverberatory furnace, where a slag containing copper silicate is formed. An improvement in this procedure is claimed by Mr. JAMES B. HERRESHOFF, JR., of New York City, in a patent which he has assigned to the Nichols Copper Co. The invention contemplates the utilization of heat formerly wasted, and the more efficient retreatment of the reverberatory slag.

Using two basic converters, silicious material and matte are blown in the first one until a clean fusible slag is made containing part of the iron in the matte. This slag is removed and silicious material added in excess of the requirements of the remaining iron. The blow is continued until all the iron has been slagged and white metal produced. The slag and excess silica are now a viscous mass, from beneath which the white metal is poured and transferred to the second converter and blown to blister copper. A new charge of matte is then added to the viscous slag in the first converter and the process repeated. By this method the silicious material is heated by the bath or charge, and when brought into contact with the next charge of matte tends to raise its temperature instead of cooling it. Another advantage claimed is that cleaner slags are produced, because at no time is slag poured from a bath of copper. The reverberatory slag mentioned above can be used to advantage as silicious flux in the converting operation. (1,103,925, July 14.)

### Alloys

**An alloy of tungsten and nickel,** having the property of ductility, and from which the nickel can be completely removed without resort to fusion, is patented by Mr. HANS KREUSLER, of Wilmersdorf, near Berlin, Germany. The alloy and the method of making it are specially applicable to the production of metallic tungsten filaments for incandescent electric lamps. Alloys of 90 per cent tungsten and 10 per cent nickel prove to be of special utility. The nickel can be driven from finely drawn wires of such an alloy by subjecting them to heat in a highly rarefied atmosphere or in a vacuum, as by passing an electric current through them. The resulting tungsten wires can be used as lamp filaments. (1,110,303, Sept. 8.)

# The Electric Crane in the Electrolytic Copper Refinery

In several branches of the metallurgical industry the electric traveling crane has virtually become a part of the process and performs various functions aside from the transportation of materials. It would be difficult to conceive of an open-hearth steel works without the several distinctive types of electric cranes that have been developed along with the mill practice, and somewhat analogous conditions prevail in modern plate glass works and particularly in the "casting-hall" where large crucibles of molten glass are withdrawn from the furnaces and poured by electric traveling cranes of special construction.

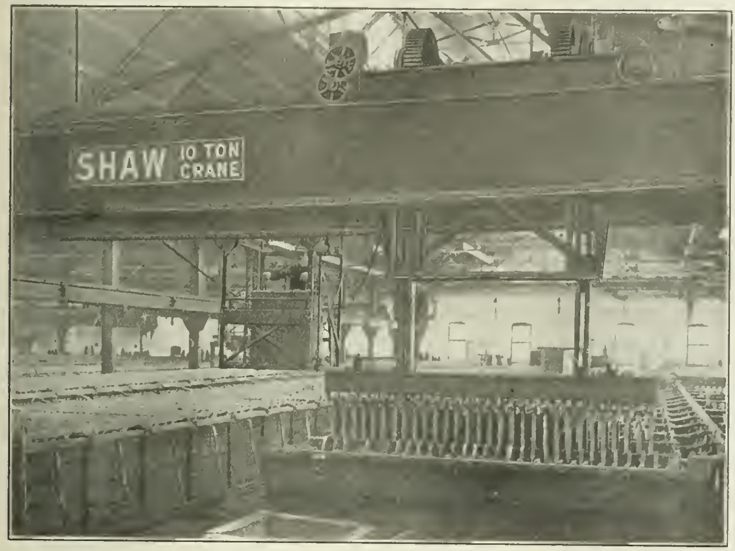

FIG. 1—PLACING THE ANODES IN THE ELECTROLYTIC TANK

The crane shown in the accompanying illustrations is employed for the single purpose of handling the electrodes of electrolytic copper refining tanks. The lifting frame comprises two parallel I-beams from each of which depends a series of hooks which engage the supporting lugs on the electrodes. With the lifting frame lowered into position, a slight movement of the trolley or carriage along the bridge serves to engage the hooks and the entire anode or cathode content of the tank is then lifted in the one operation.

The distinctive feature of this crane is the rigid-bar hoist, the two vertical bars supporting the lifting frame and traveling in heavily braced guides as shown in the illustration. The principal advantage lies in the fact that the lifting frame cannot possibly tilt and drop the electrodes, even if the load is unbalanced, while at the same time all tendency of the load to sway due to the travel motions is effectively resisted.

This crane has three independent motors for respectively the hoist, the cross travel of the trolley and the longitudinal travel of the entire crane along the runway. The operator's cage is supported from one of the bridge girders and at the center of the span, and the speed and accuracy attained by an experienced operator are little short of amazing.

Prior to delivery in the tank house each group of thirty anode castings is assembled in racks on a transfer car, the anodes being correctly spaced with reference to the position of the hooks on the lifting frame.

Fig. 1 shows the operation of the crane while placing the anodes in the electrolytic tank.

Fig. 2 shows the crane with a lot of refined copper cathodes immediately after removal from the electrolytic tank.

The illustrations are from photographs made at the works of the United States Metals Refining Company at Chrome, N. J.

The cranes were built by the Shaw Electric Crane Company, one of the subsidiaries of Manning, Maxwell & Moore, Inc.

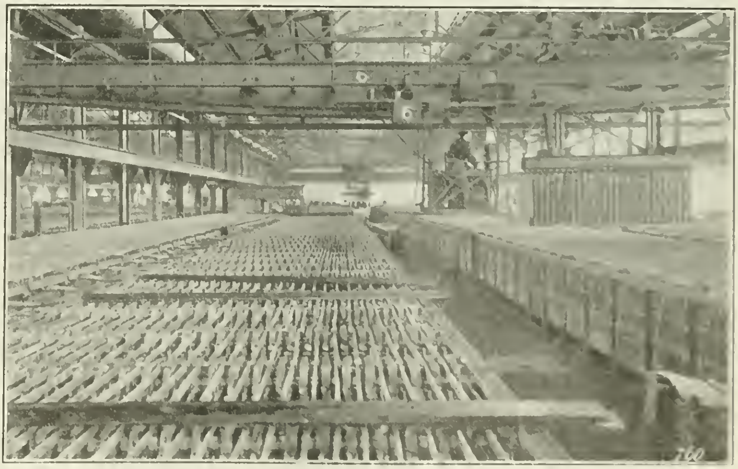

FIG. 2—CRANE WITH CATHODES AFTER REMOVAL FROM ELECTROLYTIC TANK

---

**The reported discovery of platinum** in the Boss mine in the Goodsprings, or Yellow Pine, mining district in Nevada, seems to be confirmed by the published assays of a reputable eastern firm. Palladium and gold also are said to occur with the platinum, giving an ore of unusual value.

## Calorizing

### Coating Metals with a Layer of Aluminium Alloy for Protection Against High Temperatures

H. B. C. Allison and L. A. Hawkins, of the Research Laboratory of the General Electric Company, Schenectady, N. Y., have published an interesting article on "Calorizing" in the October issue of the *General Electric Review*, from which the following notes are taken.

Mr. T. Van Aller discovered a process of heating metals in revolving drums with mixtures containing, among other things, finely ground aluminium, by which a surface alloy containing aluminium is produced (From this it would seem that the process, in its principle is similar to sherardizing. See our Vol. V, page 187, and VI, page 191.) In the case of copper, this alloy is of the nature of an aluminium bronze, but richer in aluminium than the ordinary alloy of that name and more resistant to heat, so that copper thus treated is protected up to the melting period of the alloy from the scaling which occurs when untreated copper is heated above 300 deg. C. The same general result was obtained in the case of iron and steel. Some use was made of this process, which was called "calorizing," for treating copper soldering irons and iron resistance wires for heating devices.

Modifications of the process, extending it to further applications, were made by Mr. E. G. Gilson, of the Schenectady Research Laboratory. Pieces which, because of their shape or size, are not adapted for tumbling, may be calorized by packing them in, or painting them with, a suitable mixture, and heating them. Thus, the size of the heater is the only limitation on the size of the piece that may be calorized. Wire or ribbon may be treated by a continuous process, by passing it through a heated pipe containing the proper calorizing mixture.

There appear to be many places where it is desirable to use iron vessels or apparatus at temperatures above red heat, and at such temperatures, ordinary iron rapidly oxidizes and scales away. After iron is calorized the effect of heating is slight. Instead of burning and the scale falling off, as in the case of untreated iron, practically no effect can be detected after a considerable time—certainly none which injures the surface.

Another application of this process is to iron wire or ribbon such as is used in electrical heating units. An untreated piece of this ribbon will burn out in four or five hours at the most, whereas tests upon calorized pieces have shown that the life is increased at least fifty fold, and in the best instances over one hundred fold. The results of tests made at Pittsfield indicate that a life of over 500 hours may be expected from calorized heating units run at a temperature of 800 deg. C.

Calorized seamless iron tubing is being used for combustion tubes in the research analytical laboratory where pure oxygen is brought in contact with the metal, at temperatures from 900 to 1000 deg. C. These are thus far operated all right and still appear unaltered after nearly 100 hours' use.

The above facts seem to indicate that this is a simple method for extending the use of iron under oxidizing conditions at high temperatures, and for greatly prolonging the life in those instances where it is now used but must be renewed at frequent intervals. In the case of small mufflers or crucibles, where temperatures are below 1000 deg. C., this treatment of cheap cast or wrought-iron shapes seems very promising. While the life of the coating depends on the temperature at which it is used, as well as on the duration of time taken in its preparation, i.e., the quantity of aluminium which alloys with the surface of the iron, it does not permit of long use at temperatures much in excess of 1100 deg. C.

Copper parts also, which are exposed to high temperature, can have their life increased by calorizing. In some cases calorized copper may be used advantageously in place of aluminium bronze. For instance, a large power station had trouble from early corrosion of its condenser tubes. These tubes were aluminium bronze and were supposed to last at least a year. As a matter of fact, while occasionally tubes would last as long as six years, other tubes would fail in four to six weeks after they had been installed. About two and a half years ago a set of calorized copper tubes was installed and so far not a tube has failed.

In some cases the life of copper contacts can be increased by calorizing. For instance, a set of railway controller contacts which were calorized showed double the life of the ordinary untreated contacts.

As has been said, the effect of calorizing is to produce a surface alloy containing aluminium. The thickness of this alloy varies with the length of time during which the piece is subjected to the calorizing process, and the percentage of aluminium varies through the coating, being greatest at the surface. This is shown clearly by a cross-section of a calorized copper rod. The line between the alloy and the unchanged copper is sharp, but the color of the alloy varies from a rich golden-yellow next to the copper to a silvery-white at the surface.

When an iron pipe or ribbon is calorized for a heating unit, a portion of the iron becomes alloyed with the aluminium. Naturally this results in changing both the resistance and the temperature coefficient. The thicker the calorizing coat the greater is the change. This is shown by Table 1, in which No. 1 was given a lighter coat than No. 2.

Table I

| Sample | Ohms per M (19°) | Temp. Co-Ef. Elec. Resis. (O — 150°) × $10^{-3}$ |
|---|---|---|
| Iron ribbon | 0.905 | 5.61 |
| Same calorized, No. 1 | 2.45 | 1.72 |
| Same calorized, No. 2 | 7.6 | 0.151 |

A thin ribbon may easily be calorized all the way through, and then becomes quite brittle.

The dimensions and weight of either a copper or iron piece are slightly increased by calorizing. The increase of dimension is much less than the thickness of the alloy coat, the greater part of which simply takes the place of the original metal. The dimensions may, however, increase several mils and there is a tendency to a greater increases at the edges than on flat surfaces.

For iron, calorizing is intended only for protection at high temperatures. It does not compete with galvanizing, sherardizing, and other similar processes for protection against oxidation or corrosion at low temperatures. Its usefulness lies within a range of temperature much higher than a galvanized or sherardized coat could stand.

For copper, calorizing is effective against corrosion at low temperature as well as against oxidation at high temperature. The upper limit is determined by the melting point of the alloy, which is somewhat lower the heavier the calorizing treatment, since that means an alloy with a higher aluminium content.

The probable explanation of the effect of the aluminium in the surface alloy is that a thin coat of alumina forms which prevents further burning of the metal beneath. It is well known that a pure aluminium wire may be heated in the air to a temperature several hundred degrees above its melting-point, without flowing, when the thin alumina shell which surrounds and supports the molten metal is easily seen.

The orginal article in the *General Electric Review* contains some interesting microphotographs.

# Present Status of the Fink Furnace

BY H. B. PULSIFER

The Fink furnace has now been before the public in various ways for some years. In view of the fact that no large commercial units are operating, while the Fink Smelters Company yet claims to have a valuable addition to metallurgical equipment, this contribution is offered as recording some of the difficulties encountered in trying to improve metallurgical practice and get more value from some ores and some value from ores as yet practically worthless.

### Patents

The Fink furnace is presented by men who are not at present engaged in the smelting industry; that is, they have no works of their own in which the furnace could be placed and put to work as a matter of regular routine. A very large amount of money has been expended on the evolution of the furnace and its operation, so that to secure the investment and legitimate profit every detail possible has been patented. The securing of domestic and foreign patents has consumed much valuable time and delayed matters at several times when otherwise much progress might have been made.

Patents on metallurgical devices are being issued these days and upheld years after they have been applied for; the Fink sponsors have not seen fit to attempt other than the most open and conservative business policy. The matter of foreign patents has more than once caused delay; at this very moment accessory equipment promising increased usefulness to the furnace proper awaits patent issues in countries so disturbed by the war that business and communication are paralyzed. Whether or not obtaining patents be accepted as the best possible course, the Fink company has chosen this course and has experienced this trouble.

### Suitable Raw Material

The ideas of the peculiar field for a furnace of this type have considerably changed since the early days of Mr. Fink's efforts at smelting copper concentrates. It is realized that the type of furnace is hardly adapted to compete with the regular methods employing large units for smelting copper ores. On the other hand, it has become more and more evident that the furnace has a special field in that it can assimilate a mixed sulphide ore and separate it into three parts, two of which are valuable while the third is barren and holds the undesirable constituents of the original ore. It is the method of treatment which produces a volatile, condensible portion containing zinc and lead; a matte or metal containing copper and precious metals, and a slag of customary composition devoid of appreciable value.

With the growth of the idea that the furnace could not compete with larger units on simple ores the aim has been to place furnaces where their success would be pronounced and permanent.

Available ore-deposits and abundant raw material have not lacked from this point of view. The countries of the globe are profusely supplied with ores which are going begging at the present time. Great deposits of metal-bearing materials, the individual metals of which would be worth from $20 to $100 per ton of raw dirt, are idle or awaiting the proper treatment method. Other ores are today sold in great quantities for small fractions of their metallic values because one metal is thrown away to get another, or separation is extravagantly costly.

The Fink company has not been in a position to acquire any of these numerous deposits, exploit the mine, build the plant, smelt the ore and enter the metal-selling field. Such operations demand almost unlimited capital, besides several varieties of managerial resources; the company has appreciated this phase and refrained.

### Sympathetic Hands

With this plethora of raw material available it is not difficult to imagine that numerous companies would be only too glad to take over and use the process; such is the case. Numerous concerns are only awaiting the opportunity to make the effort and reap the benefit. A review of such cases, or the ease with which sufficient capital may be acquired, wonderfully enhances one's already vigorous conception of the greed of man. The Fink company wants to control the furnace sufficiently to insure its future and get a fair proportion of any profits.

Metallurgists are only too well aware of the difficulty in introducing new equipment and getting it treated in proper manner; many a fine invention is thrown down and out by some brute, for some minor defect, through prejudice; the most perfect machine or beautiful process usually requires patient and sympathetic coaxing until its operation is perfect and its intended operators learn that they are to accept it and keep it in shape.

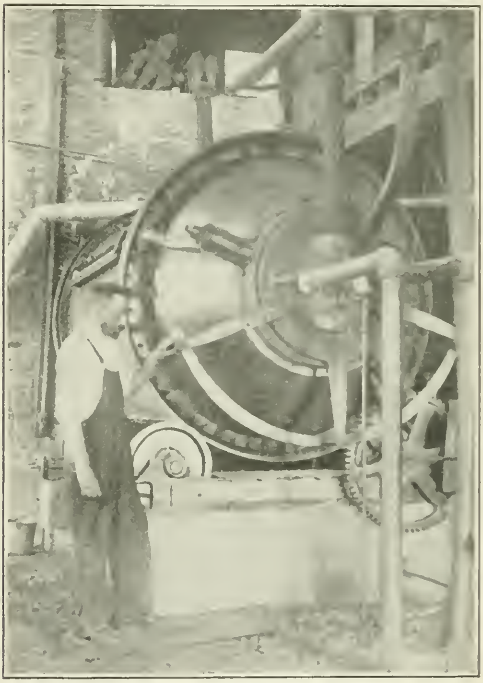

FIG. 1—FINK FURNACE IN OPERATION

On this basis many opportunities have not been considered where it was obvious that merely perfunctory attention could be expected. The Fink company does not intend to place any of its equipment in irresponsible hands.

### Plants Contracted For

About a year ago the Fink company entered into contract with the owners of the Teziutlan Copper Co., mines and plant in Puebla, Mexico, with every promise of seeing several of the Fink furnaces in prompt use under desirable conditions. Shortly after preparations were started the plant was forced to close down by war conditions; from that time the plant has been idle and no work possible.

During April, 1914, contract was made with the Mond Nickel Co., plant at Coniston, Ontario; furnace was shipped and installed and dried out for firing up. Almost on the minute of charging, cables closed the entire plant due to England's entering the war in this last August.

With both of these companies the contracts were desirable, the raw material abundant and competent technical staff on hand to insure a fair trial for commercial success.

Negotiations are at present under way with yet other companies and it is hoped that before long adequate trial of the furnace will be made to demonstrate its usefulness or otherwise. No runs sufficiently long to demonstrate working costs, life of lining or routine recovery have taken place as yet. Numerous trial runs have led the owners to believe that their confidence in the usefulness of the furnace is not misplaced.

### A Recent Trial Run

The experimental furnace is situated at Wauwatosa, Wisconsin; unfortunately no adequate provision is made for collecting the fume. The following quotations from a report made on a run during August indicate the work the furnace can do.

"The Fink furnace is specially designed for the direct smelting of sulphide ores, being a converter-type furnace, using with equal facility either oil (crude or fuel), gas (natural or producer), or soft coal for fuel.

"It has three or more sets of tuyeres as seen in the accompanying drawing. These are spaced so as to leave at least one position of the furnace in which all of the tuyeres will be found above the tap-hole. This is very essential, for in smelting an ore of the mixed type it often becomes necessary to use the furnace for a time as a reverberatory, and this can be accomplished by simply bringing the tuyeres above the charge, shutting off the high-pressure air, and continuing the oil in order to heat the furnace. The opening and closing of the tuyeres is regulated by means of a cam, and only when any particular set of tuyeres is passing underneath the charge is the full air supply permitted to enter this tuyere box.

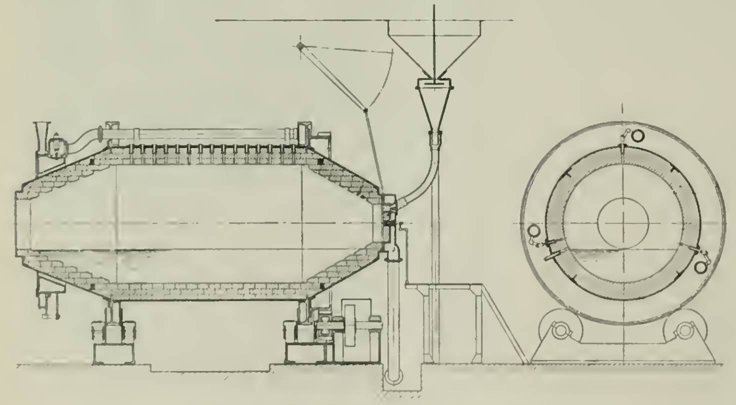

FIG 2—FINK SMELTING FURNACE

"The ore is fed, either continuously or intermittently, through a feed pipe which fits into a stationary door, containing also openings for the introduction of the burner nozzle as well as for the supply of additional air. The waste gases and fumes pass out at the opposite end.

"After the furnace is once brought to a smelting heat, the ore is fed, and rapid desulphurization commences immediately. When the carrying capacity of the furnace has been reached, the reduction is continued until the desired elimination of the zinc and lead have been obtained. The desulphurization of the zinc is not brought about entirely through the action of the tuyeres, as the low-pressure air supplied to the furnace for the combustion of the fuel also plays an important part in the oxidation. Whenever the tuyeres pass underneath the charge a fine spray of molten ore and matte is thrown up against the walls of the furnace. This spray, when it meets the stream of low-pressure air supplied from the end of the furnace, is in an ideal physical condition for rapid oxidation.

"The lead is driven off almost as fast as the ore is melted. However, the zinc requires more time for its elimination. As the sulphur continues to grow less in the charge, it is necessary to supply more fuel, as the tuyeres are no longer operating at full efficiency. It is now desirable to supply additional sulphide ore, free from zinc, if possible, to restore the activity of the tuyeres and to bring about the removal of the remaining zinc.

"While the air supplied through the tuyeres is primarily for the purpose of oxidizing the sulphides in the charge, it also materially assists in driving off the lead and zinc. This action is purely physical and wholly apart from the oxidizing effect of the air, and may be compared, in its effect, to the increased volatilization noticed when passing an inert gas over molten metal.

### Analysis of the Ore

"We have used the analysis made by us as the basis of all of our calculations. Where 'Not determined' we have substituted their figures.

All calculations are based on the short ton of 2000 lb.

### Method of Treatment

"The method of treatment proposed for handling this ore contemplates its smelting in the Fink furnace for the purpose of eliminating, by volatilization, the lead and zinc together with a portion of the silver contained, and the recovery in the matte of the copper, cobalt and gold together with the remaining silver.

The volatilized metals, which are largely in the form of sulphates and oxides, are collected for separation and further treatment.

### Furnace Performance

"In all, 9000 lb. of the ore in question was received. Of this amount 8000 lb. was taken for treatment.

"The material for trial analyzed as follows:

| | *Analysis by Owners* | *Analysis by Fink Smelters Co.* |
|---|---|---|
| Lead | 22.54% | 22.38% |
| Arsenic | .08 | Not determined |
| Copper | .20 | Trace |
| Zinc | 33.29 | 33.48 |
| Iron | 3.77 | 4.60 |
| Alumina | 3.36 | 3.48 |
| Silica | 9.83 | 9.46 |
| Sulphur | 24.74 | 25.10 |
| Cobalt | .87 | .78 |
| Magnesia | .25 | Not determined |
| Lime | .17 | Not determined |
| Silver (long ton) | 18.7 oz. | (short ton) 16.7 oz. |
| Gold | Trace | Not determined |

"The run was made on Thursday, Aug. 27, 1914, beginning at 8 o'clock a. m. with a cold furnace. The run ended at 9:20 in the evening with the tapping of the slag.

"Crude oil, pre-heated, at a pressure of about 60 lb., was supplied through a spray nozzle. The air pressure as supplied through the tuyeres varied from 5 to 7 lb. and the blower delivered approximately 600 cu. ft. per minute.

"At 11:30 a. m. the furnace was at a red heat and 500 lb. of ore was charged. At noon 500 lb. was added, and 1000 lb. between 12:15 and 12:45. At 1:20 a ton was fed into the furnace; another ton was added at 2:15 and the fourth and last ton at 3:10.

"At 6 p. m. 50 lb. of coal was added and at 6:30, 100 lb. more; the furnace heat increased and zinc elimination was strong. At 8:40 35 lb. of coal was added and blowing continued until at 9:20 the slag was tapped and the run ended.

"The total amount of oil consumed during the run was 132 gal., equivalent to 33 gal. per ton of ore smelted. When it is considered that the proper smelting temperature was not attained until toward the end of the operation it is obvious that most of the oil was used in heating the furnace and not in smelting the ore. Much less would be required per ton in continuous smelting.

### Recoveries

"The slag amounted to 1780 lbs.; it analyzed:

| | |
|---|---|
| Zinc | 14.5% |
| Lead | 0.5 |
| Silver | 16. oz. |

Some of the fume analyzed:

| | |
|---|---|
| Zinc | 24.5% |
| Lead | 34.6 |
| Silver | 15. oz. |

"The original ore contained 33.48 per cent zinc, or a total of 2678.4 lb. in the ore charged; and the slag contained only 14.5 per cent zinc, or 258 lb.; hence 2420 lb. of zinc was eliminated during the run, which is equivalent to a trifle over 90 per cent of the total.

"The original ore also showed 22.38 per cent lead, or a total of 1790.4 lb. in the ore charged, and the slag contained 0.5 per cent lead, or 8.9 lb. The elimination of the lead was almost perfect.

"That portion of the slag carrying the matte was separately assayed for silver and showed 18 oz. per ton. Since the original ore carries 16.7 oz. silver per ton, or a total of 66.8 oz. for the four tons treated, and the 1780 lb. of slag carried about 16 oz. of silver per ton, it is evident that about 78.6 per cent of the silver had been volatilized with the lead and zinc.

"Owing to the lack of iron in the ore, the addition of sulphides is doubly necessary to form a slag sufficiently liquid to allow of its thorough separation from the matte. At the time of making this test sulphide ore was not available, and this forms the only unsatisfactory feature of the run.

"In case it is not possible to obtain pyrite ore or concentrate to add to the furnace before tapping the charge, it will be necessary to add limestone at the commencement of the operation, so as to assure the production of a more liquid slag, whereby a better separation of the matte and silver will be obtained.

### Collection of Fume

"Substantially all of the volatilized zinc, lead, and silver which are eliminated from the furnace in the smelting operation are positively collectable as fume or concentrate in the standard form of bag-house now widely used for that purpose.

"The cost ot the regular blast-furnace plants for recovering the zinc, lead and silver products in the bag-house, where a *minimum* of fume is produced, cannot be applied to our particular case where the reverse is true, for we produce a *maximum* of fume and recover a correspondingly greater amount of product; hence our cost for this recovery per ton of product is much less.

"It is safe to say that $1 is a high estimate of the cost of recovering a ton of fume produced from the Fink furnace, which would represent for this mixed type of ore about 70 cents per ton of charge treated. In a large installation this cost could undoubtedly be materially reduced.

"The bag-house product in the case of this ore would be an impure zinc oxide, mixed with lead sulphate, and carrying that part of the silver that has not been taken up by the matte in the furnace, or contained in the slag, and would be of a somewhat different composition to that of the product secured in this particular run, inasmuch as the zinc and silver being lighter when passed directly through the stack did not condense as rapidly as the heavier lead sulphate.

### Costs

"As to the costs of the smelting operation, it may be stated in general that this is largely governed by local conditions. If oil may be had for 3 cents per gallon, the fuel item for smelting purposes alone would not exceed 60 cents per ton of charge.

"The attendance is about the same as that required for handling the ordinary basic converter, and three men on a shift would be more than ample to serve a 100-ton furnace. As the ore-feed is automatic, the sole labor, aside from the preliminary handling of the ore, consists in tapping the furnace, oiling the machinery, and collecting the recovered products.

"The following, by way of a summary, is an approximate estimate (exclusive of interest, depreciation and overhead) of the cost per ton of smelting the mixed ore in the Fink furnace, based on a daily capacity of 100 tons, beginning with the crushing of the ore to 2-in. size, and ending with the elimination of the volatile products from the furnace, and the recovery of the copper-cobalt matte carrying the gold and that portion of the silver not taken over with the fume or carried in the slag:

| | Cost per Ton |
|---|---|
| Crushing | $0.05 |
| Electric power, including machine shop, lighting, etc., at $40 per hp per year | .55 |
| Labor—3 shifts of 1 furnace tender at $3.50 and 1 laborer at $2.50; 2 shifts, 1 engineer at $3.50; total $25 per 24 hours | .25 |
| Superintendent at $3,600 and clerk hire at $1,200, $4,800 per year | .13 |
| Oil, 20 gallons at 3 cts | .60 |
| Total | $1.58 |

Whether we agree with the Fink company in regard to its costs, or not, and whatever view we may take of the ease or difficulty of turning the fume into commercial products, we have to admit that in this case a raw ore of the most refractory nature has been broken up and put a long way on its course to complete usefulness without any flux. This particular ore has a homogeneous steel-gray appearance and is absolutely beyond physical separation. It is undesired by either lead or zinc smelter and has almost no commercial value. Should the actual operating costs come anywhere near the estimates, the furnace is of remarkable promise.

Chicago, Ill.

---

The new concentrating mill of the Daly West Mining Co., at Park City, Utah, was expected to be ready for operation about October 15.

The Werner & Pfleiderer Company, the well-known makers of machinery for the chemical industry, are increasing their manufacturing facilities by the addition of an up-to-date extension to their foundry at their factory in Saginaw, Mich.

## Gas-Blowing Engines

The Mesta Machine Company of Pittsburgh, Pa., are now building for the Pennsylvania Steel Company of Steelton, Pa., two gas-blowing engines of 46-in. and 84-in. cylinder diameters and 60-in. stroke. These engines are believed to be the largest gas-blowing engines ever built in the United States or on the American continent.

The gas cylinders and blowing cylinder are arranged in tandem; that is to say, the air cylinder is directly back of the gas cylinder. This arrangement has never been used in the United States but has been universally adopted by European gas engine builders. Undoubtedly this arrangement makes possible a much simpler design of the whole engines.

Another innovation as far as American gas engines are concerned is the use of a center crank instead of an overhung crank. While it is possible to build large engines with overhung cranks, it is considered that the center crank provides a more rigid construction; all of their large reversing engines have been built with center cranks and have been universally successful.

Finally, the blowing tub is equipped with the well known Mesta automatic plate valve (Iversen patent) which, since its introduction in 1911, has been a complete success. With these valves the efficiency of the air end is greatly increased and the cost of maintenance and repairs reduced to practically nothing, as all complicated valve gear is eliminated.

## Rapid Cyanidation of Ores

The American Rapid Cyaniding Company of Detroit, Mich., reports that they have installed a Reinohl rapid cyaniding apparatus at the Suffolk Mill, Ophir, San Miguel County, Colorado, operated by the Ophir Gold Mines, Milling and Power Company, Mr. George B. Pickett, vice-president and general manager.

Ore is run from a bin through crushers, then to a stamp mill, where it is further crushed in a cyanide solution, and conducted through a tube mill and reduced to about two hundred mesh. The pulp is then delivered to a Reinohl apparatus, comprising a launder and lixiviator, where the pulp is heated, additional cyanide supplied progressively to maintain its strength, and the pulp continuously agitated in the presence of the oxygen of the atmosphere, until contact is formed between the values and the solution.

From the end of the lixiviator the pulp is conducted to settling tanks, clarified solution bearing the values decanted, filtered and conducted through zinc shaving boxes in the usual manner. A complete cycle, from the ore bins, through the stamps, the tube mills, the Reinohl launder and lixiviator to a settling tank, clarified solution decanted from another settling tank, passed through a filter, into and through the zinc boxes, and the solution returned to the stock tank, was made in eleven minutes. Previous practice, by other cyaniding processes, required four days to accomplish the same result.

Recoveries indicated 96 per cent of the gold and 98 per cent of the silver in the ores, at a loss of 5 per cent of the strength of the solution.

Demonstrations of the process and apparatus were in charge of A. J. Weinig, engineer metallurgist of the Liberty Bell Mining and Milling Company, Telluride, Colorado, and Mr. Walter L. Reid, cyaniding engineer of the Smuggler Union Mill, Telluride, witnessed the plant in operation. The inventor, D. C. Reinohl, of Washington, D. C., superintended the installation of the apparatus, assisted by David W. Reinohl and Wesley B. Sibley.

## Obituary

**Curtis E. Whittlesey**, for many years treasurer and secretary of the McGraw Publishing Company, Inc., died at his home in Madison, N. J., on Friday, Oct. 9, 1914, in his seventy-second year. Though he had been ill of pneumonia for several days, the end came suddenly.

Mr. Whittlesey was born near Rochester in 1842. As a young man he entered business in Corfu, N. Y., where his industry and capacity brought him early success. In 1890 he joined James H. McGraw as a member of the firm which was the publisher at that time of the *Street Railway Journal*, and which, as the present McGraw Publishing Company, Inc., became also the publisher of the *Electrical World*, *Engineering Record*, and METALLURGICAL AND CHEMICAL ENGINEERING. Mr. Whittlesey had also been the treasurer of the Electrochemical Publishing Company, the former publisher of METALLURGICAL AND CHEMICAL ENGINEERING, from its early days as *Electrochemical Industry*. He was a wise counselor, conservative in his fundamental principles on the ideals of technical journalism, yet progressive in the deep personal interest which he took in the career of this journal and its ever broadening editorial scope and influence. All the members of the staff of this journal are indebted to him for innumerable kind words and acts of sympathy, advice, and encouragement.

During the twenty-four years of association with the McGraw Publishing Company Mr. Whittlesey had become widely known as a man of great experience in business affairs, and his wisdom and unerring judgment were constantly consulted not only in the affairs of the company, which he had done so much successfully to establish, but by many individuals who had come thoroughly to value his opinions on commercial and financial questions. Although his passing came with the ripeness of years, it is deeply lamented by a host of friends, many of them close business associaates, who loved and honored him. It was impossible to have even the most cursory relationship with him without being impressed by his lovable qualities and sterling character.

Mr. Whittlesey was keenly interested in church work, and was for years an elder and the treasurer of the Presbyterian Chuch at Madison, N. J.

He leaves a widow and three daughters, Mrs. Carl A. Felt, wife of the Rev. Carl A. Felt, of the Pekin University, China; Mrs. James H. McGraw, wife of the president of the McGraw Publishing Company, Inc., and Mrs. Robert E. Harned, wife of the Rev. Robert E. Harned, librarian of the Drew Theological Seminary, Madison, N. J.

* * *

**Thomas Johnston Grier**, superintendent of the Homestake Mining Co., died on the evening of September 22, 1914, at Los Angeles, Cal., where he had been with members of his family for several weeks. Although his intimate friends and associates knew that his heart was weak and that his passing would be sudden, nevertheless the news of his death came unexpectedly.

Mr. Grier was born in Pakenham, Ontario, in 1850, being the fourth of a family of ten children. He received his education in the graded and high schools of Iroquois, Ontario, and at the age of 17 learned telegraphy and was employed as an operator at Montreal. Later he removed to Corinne, Utah, and again to Salt Lake City, where he continued in the same line of work. In 1878 he entered the employ of the Homestake Mining Company at Lead, S. D., in the capacity of a telegrapher and clerk. He gradually assumed increased responsibility, and at various times was in full charge of operations during the absence of Mr. Samuel McMaster, who was then superintendent. On the death of Mr. McMaster in 1884, Mr. Grier was appointed superintendent and held that position for thirty years.

In 1886 he was married to Mary Jane Palethorpe, of Glasgow, Scotland. He is survived by his widow, a daughter and three sons.

His rise to the place of one of the foremost figures in America mining and metallurgy was from humble beginnings, and practically without that specific preliminary training which might be considered necessary. The record of his work, however, shows native ability of an unusual order in the conception and execution of large undertakings. It shows also his appreciation of, and consideration for, the human element in business, for he was always mindful of the interest and condition of his employees and made many contributions to their welfare.

It was during his term of office that the Homestake company developed into the prosperous organization that is so well known today. He directed and completed vast improvements, such as the water system that supplies the company's works, the town of Lead and several surrounding settlements. The hydroelectric power plant at Spearfish, the Ellison hoist, the Star and Amicus mills, the slime plant at Deadwood, and the viaduct connecting the mills with the company's railway system, all were completed under Mr. Grier's direction. During this period the extent of the company's operations increased greatly: the number of employees rose to about 2500 and the monthly pay roll to $250,000; the quantity of ore mined and milled reached nearly 4500 tons per day, but the management remained under his sole direction and to his discretion was left the entire policy of the company.

A suggestion of Mr. Grier's broad interest in general affairs is found in his relations outside the Homestake Mining Company. He was president of the First National Bank of Lead, vice-president of the First National Bank of Deadwood, vice-president and director of the Wasp No. 2 Mining Company and president of the Hearst Mercantile Company. He was also a charter member of the Homestake Veteran's Association, belonged to several Masonic orders and the Benevolent Protective Order of Elks. In 1892 he was elected to membership in the American Institute of Mining Engineers.

The Homestake company's policy of improving the condition of its employees and looking to their welfare is a personal tribute to the man who was its operative head for thirty years. Mr. Grier was always accessible to any employee who sought advice or a sympathetic hearing on any matter. As one of his associates has said, "in addition to his great ability, he was quite the most lovable man it has ever been my good fortune to know." Among the institutions established by the company is the hospital, the service of which is free to employees and their dependents. An Aid Fund, to which employees contribute $1 each per month, is supported by the company to the extent of $1,000 per month. This fund provides benefits in case of accident, illness or death. Recreation Hall, erected by the company at a cost of $300,000, affords a place of amusement and recreation for employees and contains the Hearst free library. Mr. Grier's interest in all these developments gave the company an enviable reputation for consideration of those who helped daily to make it one of the most famous mining organizations in the world.

In August last the Federal Commission on Industrial Relations held a hearing at Deadwood, at which Mr. Grier and others gave testimony. At the close of the hearing the chairman of the Commission made the following comment on Mr. Grier's remarks:

> "You have here the most remarkable business organization that I have come across in the country. You have developed welfare features which are beyond anything that I know of, and they are given with a liberal hand. You have a high scale of wages, reasonable hours—very fair hours. There has been evidently great progress made in taking care of the employees in the hospital service, and you have taken care of the cost of living, have kept it down below what employees in other communities have been forced to pay. You have practically been able by your great strength here as a huge corporation, dominating the whole community, to look out for the welfare of your employees, and to bring in an admirable class of citizens. It seems also that you are influential in politics, that you secure a good class of officials, and that you have secured the enforcement of law, the reduction of immorality. It seems also that you make an effort to build up the religious life of the community and that your policy is broad and liberal in all respects. I take it also, that this policy depends solely upon your personality. Such inquiries as I have made here indicate that in all cases the stockholders leave all these matters to you personally, and that this broad policy has been carried out by you on your own initiative, and that you have felt that it was necessary, for the good of the community, the securing of a fine class of labor here, which you have undoubtedly done, that you should hold the reins pretty tight on this community."

Although the Homestake Mining Company has been a recognized power in the business life of Lead and the Black Hills, still under Mr. Grier's direction that power was used wisely for the benefit of the community and never for his own aggrandizement. Perhaps few men in his position would have developed the policies in which his faith was justified, but the light of his example may well serve for the guidance of others in similar positions.

## Personal

**Mr. William R. Appleby**, dean of the Minnesota School of Mines, recently visited the mining districts of British Columbia.

**Mr. Robert S. Blair** and **Mr. Albert F. Nathan** have entered into partnership under the firm name of Blair and Nathan with offices in the Liberty Tower at 55 Liberty Street, New York City. The firm will confine its practice to the soliciting and litigating of patents and trademarks. Mr. Delos G. Haynes will be associated with the firm.

**Mr. H. A. Butz**, for the past four years chief engineer of the Dominion Iron & Steel Company, Ltd., Sydney, Nova Scotia, Canada, has severed that connection owing to the company discontinuing for an indefinite period all construction work, due to the present war conditions, and he has made no definite plans for the future. He was formerly with the Garrett-Cromwell Engineering Company, Cleveland, Ohio.

**Mr. H. M. Eastman** has recently joined the technical staff of the National Radium Institute at Denver in the capacity of assistant superintendent. **Mr. Alan Leighton** is now a member of the laboratory force of the Bureau of Mines in Denver.

**Mr. Warren R. Gillard** has resigned as chemist of the Pittsburgh Testing Laboratory to accept a position as research chemist with the Pittsburgh Plate Glass Company.

**Messrs. Gould, Free and Ash**, chemical engineers, announce that Mr. Edward E. Free has retired from the firm and that the business is being continued by Mr. Ralph A. Gould and Mr. Charles S. Ash under the firm name of Gould and Ash, with offices as formerly in the Monadnock Building, San Francisco. Mr. Edward E. Free will be at the Department of Plant Physiology, John Hopkins University, Baltimore, Md.

**Mr. J. W. H. Hamilton**, of Hamilton & Hansell and the American Grondal Company, has recently returned to New York after about one year's traveling in Europe, where he supervised the installation of several Greenawalt sintering plants.

**Mr. J. E. Johnson, Jr.**, lectured before the Franklin Institute on October 8 on the subject "Recent Developments in Cast Iron Manufacture."

**Mr. Philip Nungesser**, of the Nungesser Carbon & Battery Company, Cleveland, Ohio, recently celebrated his twenty-fifth anniversary in the dry cell business. On September 7, 1889, Mr. Nungesser sold the first dozen of his cells and got 75 cents a piece for them. At that time a few cells were sold a month. The present yearly output of dry cells in this country is estimated as 40,000,000 cells.

Mr. Charles F. Rand has resigned as president and director of the Consolidated Coppermines Company.

Mr. L. Selmi has accepted the position of chief chemist-metallurgist with the Otis Steel Company, Cleveland, Ohio.

## Digest of Electrochemical U. S. Patents

PRIOR TO 1903

*Arranged according to subject-matter and in chronological order.*

*Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.*

AQUEOUS BATH (ELECTROPLATING) *Continued*

607,646, July 19, 1898, Pascal Marino, of Paris, France.

Relates to depositing metals or alloys or to extracting metals from minerals containing them, by electrolysis in a mixed electrolyte. A solution is prepared, say, of one equivalent of that metallic salt to be deposited, selecting such salts as form insoluble precipitates with barium, strontium, calcium, or lead; and another solution of a salt of a different acid of barium, strontium, calcium, or lead, containing less than one equivalent of it. These two solutions are then mixed, and, in consequence of double decomposition, an insoluble precipitate is formed, and the remaining liquid is used as the electrolyte. In order to extract copper from a mineral the electrolyte is prepared with a solution of sulfate of copper. An alkali metal surface is added to it, and it is mixed with an insufficient quantity of chloride of an alkali-earth metal, so as not to precipitate the whole of the sulfuric acid combined with the copper and the alkali. There will be formed a sulfate of the alkali-earth metal, and the liquid, decanted or filtered, will contain only a mixture of sulfate and of chloride of copper, together with a sulfate and chloride of the alkali. To improve the conductivity and to facilitate decomposition of the mineral, I add a mineral acid, such as sulfuric or hydrochloric; the mineral containing the copper is used as an anode. When using metal anodes, a carbon anode is sometimes used with the metal.

610,954, Sept. 20, 1898, Eddy T. Thomas, of New York, N. Y., assignor to Harold Binney, trustee, of same place.

Relates to electroplating large objects, such as a ship, and consists in an open-sided tank having rubber packing edges, arranged to be temporarily secured to the object, such as a ship, the tank to contain the electrolyte. The iron body of the ship is cleaned, either mechanically or chemically, the tank secured, and an alkaline electrolyte containing a cyanide is used, since this makes a better deposit upon the iron. After the cyanide deposit, a sulfate of copper solution is used, to complete the deposit. The tank is next moved to an adjoining section and secured in a position that will produce overlapping deposits upon the ship. The anodes are removably suspended in the tank.

612,250, Oct. 11, 1898, Heinrich von der Linde, of Crefeld, Germany.

Relates to the removing of electrodeposited metal, such as nickel, copper, alloys of nickel and copper, etc., by connecting the plated metal as anode in an electrolyte of ammonium carbonate; the nickel and copper are dissolved and deposited upon a suitable cathode, the iron base of the anode not being affected by the electrolysis.

621,084, March 14, 1899, Henry L. Hollis, of Chicago, Ill.

Relates to coating iron articles such as sheets with a coating that will protect the article from rust. The article to be treated is connected as an anode in an alkaline electrolyte, such as sodium hydroxide, of specific gravity 1.25 to 1.40, temperature 50 deg. to 115 deg. C., and an anode current density of from 0.005 amp to 0.30 amp per sq. in. An iron cathode may be used, the current being interrupted when the coating is completed. The article so coated is then subjected to an annealing temperature of 800 deg. to 1400 deg. F., which changes the oxide to magnetic oxide and is so intimate with the iron that sheets may be bent without affecting the condition of the coating.

625,255, May 16, 1899, Thomas Archibald Goodchild and Archibald Campbell Tait Bond, of London, England.

Relates to the production of disappearing watermarks on manufactured paper. Upon a platinum sheet, constituting the anode, is placed moistened blotting paper or other absorbent material, and on this the paper to be marked, previously moistened through with ordinary water, for example, a water containing 20 gr. of saline matter per gallon answered the purpose. A platinum cathode of the desired design is now pressed firmly on the moistened paper for from five to ten seconds, according to the paper and strength of current. On removal of the cathode a distinct and translucent image of the design apears, which gradually fades away as the paper dries, and finally becomes invisible, but may be revived by moistening the paper. It is supposed the sodium hydroxide liberated at the cathode from the saline matter in the water acts upon the paper, the latter becoming more hygroscopic at the points of contact.

## Book Review

**The Mineral Industry**, its Statistics, Technology and Trade during 1913. Edited by **G. A. Roush**, A. B., M. S., Assistant Professor, Department of Metallurgy, Lehigh University; Assistant Secretary of the American Electrochemical Society. Octavo, 1010 pages, 55 illustrations. Price, $10. New York: McGraw-Hill Book Company, Inc.

This is the twenty-second annual volume of the famous series founded by Richard P. Rothwell and continued by such well-known editors as Joseph Struthers and W. R. Ingalls. It is interesting to note in passing that the first editor was once professor of mining in Lehigh University, and that the present editor is also connected with the same institution.

The present volume fully lives up to the reputation of its predecessors. The note in the list of contributors many of the contributors to previous volumes, and also the addition of many new names which will lend added authority to its contents. Among these new names we notice L. Addicks on Electrolytic Copper Refining, H. Foster Bain on Potassium Salts, Dr. C. G. Fink on Tungsten, B. L. Miller on Graphite, T. T. Read on the Copper Hydrometallurgy, Dr. Weintraub on Boron.

The policy of the new editor has been one of consolidation of separate articles where possible under one generic heading; also to place the articles in the hands of specialists who can handle the material authoritatively, and express valuable opinions as well as compile statistical information. In succeeding volumes we may expect still further improvements of a similar nature; but taken as it is, we can judge the present volume as worthy of the best traditions of the "Mineral Industry," and a credit alike to the capacity of the contributors and the ability of the editor.

## Metallurgy in the Northwest

Montana is a wonderful mineral domain; Anaconda is a metallurgical center of the first magnitude. From it have emanated innovations in the treatment of copper ore that have commanded respect and admiration, and to it have gravitated many men with faith and hope in new schemes that loomed large as possibilities but sometimes failed of realization. Within its own organization has been maintained one of the best-equipped research departments in the country. Problems have been attacked with vigorous intelligence, and the results show what can be accomplished by an organization backed by brains, money and the progressive spirit of research.

The record of the past few years is an inspiration. Beginning with the attack on slime concentration, there was evolved the twenty-deck round table and a special application of Dorr thickeners to handle daily 2500 tons of practically 200-mesh slime contained in 26,000,000 gal. of pulp. Then came the leaching experiments on sand tailing, proved on a large scale in an 80-ton unit and followed by the erection of a 2500-ton plant. The cheap production of sulphuric acid ensued as a natural development of the leaching process; and as an abundance of this material can be produced, far in excess of the demand for leaching, it is reported that the manufacture of phosphate fertilizer will be undertaken to consume the excess. Flotation is now engaging the attention of the staff and tests are being made on Minerals Separation and Callow processes. Active work on the smelter-fume problem is affording interesting developments of the Cottrell electric precipitation process, one of which is the use of pipe-treaters up to 4 ft. in diameter. The successful evolution of this method of handling fume may result in abandoning the extensive flue system and the erection of a new stack that will surpass in dimensions all previous construction of this type.

So much for copper in Montana. In the adjoining state of Idaho there is evidence that metallurgy may cut a large figure in the Coeur d'Alene lead district, where ore-dressing has held full sway. The Bunker Hill & Sullivan company has been experimenting with dry chlorination, and the president of that concern recently declared that the anticipated success of the process would mean for the Coeur d'Alenes the production of metals instead of concentrates. We hope his vision may be realized. In this connection a word of caution may not be out of place. Coeur d'Alene operators are skilled in ore-dressing; but chemistry applied to ore treatment is a very different matter, and it will require a new group of men skilled in the art to bring success. The great variety of effective work done at Anaconda is due to an organization of specialists; the same conditions must obtain in Idaho.

## Passing the Buck

A paper on a technical subject was promised for a recent joint meeting of the New York sections of several scientific societies. It was duly passed upon, as commercially harmless, by the company with which the author was connected; but presentation was prohibited at the last moment by another company with patent working arrangements with the first one.

This reminds us of the permits which are given to war correspondents by one of the allied powers and regretfully countermanded by the others.

## The By-product of a Chemical Reaction

The *Mining Magazine*, of London, comments on our editorial on the European war, but deals almost exclusively with matters which we neither said nor suggested nor hinted at. We leave the relevance and good taste of the comment of our London critic entirely to the judgment of our readers, who have our original remarks on record in our September issue for comparison of quotations and interpretation. We have no reason to modify in the least our opinions there expressed. We publish the *Mining Magazine's* comment in full as an illustration of the correctness and pertinence of our original sketch of the psychological situation:

> "Our sympathy goes to Mr. E. F. Roeber, Ph.D., editor of *Metallurgical and Chemical Engineering*. We met him last at the American Institute dinner and meeting called to do honor to Dr. Friedrich Kolbeck, of the Freiberg Mining Academy, at New York, last May. The affair had a pronounced German flavor, from the chairman's German accent to Dr. Kolbeck's speech in German, but that was no blemish then; we were glad to be present and to participate in paying a deserved compliment to the worthy representative of the great German mining school. In the September issue of his periodical, Dr. Roeber concludes that "all Europeans have suddenly gone crazy." He speaks of "crowds and nations that act under the blind forces of Nature." The war, to our genial acquaintance at New York, is a "gigantic human reaction" in which "the most celebrated individualities do not seem to have much more freedom of will than the 'free' ions of the dissociation theory." This may be a delightful chemical simile, but to us it is flavored too much with that pestilent Prussian notion that war is a 'biological necessity,' that the breaking of a treaty is condoned by necessity, that atrocities are another part of warlike necessity, and so forth, to the end of the ensanguined chapter of mad militarism. No, Dr. Roeber, this will not do. The prevalence of such ideas among educated Germans, the acquiescence of university professors in the sinister writings of the Treitschke and Nietzsche school, and the lack of protest against the vaporings of the Potsdam War-Lord are among the causes of this great catastrophe. To us the preaching of organized murder in terms of culture is an abominable impertinence. Nay more, the violation of women, the hacking of young mothers' breasts, the murder of little children, the burning of helpless captives, the shooting of inoffensive peasants in the field may be acts of individual savagery for which the General Staff and the Kaiser are not responsible, but the sacking of Louvain and the destruction of Rheims cathedral, together with several other atrocities on a large scale, are the acts of high authority, for which no excuse has been, or can be, offered. In the face of such wanton barbarism, the chemical simile of 'necessity' is an insult to human intelligence."

## Local Section Meetings

The tendency toward centralization of the activity of the national scientific and engineering societies is justified to a certain extent, but should never go so far as to detract from the great importance of the work of local sections. No legitimate expense for the conduct of the local sections should be considered too big. Local sections can accomplish in an informal way a great deal that cannot be done in a formal way nor with the necessarily cumbersome machinery of the national society.

We are glad to note the excellent work of the New York sections of the different chemical societies. Last winter the New York section of the American Electrochemical Society, under Mr. Addicks' chairmanship, did really important pioneer work in holding a series of very enjoyable and profitable joint meetings not only with the other chemical societies, but with the mining engineers, the electrical engineers, and the mechanical engineers. His present successor, Dr. Fink, followed ably with a joint meeting with the Illuminating Engineering Society and the Gas Institute, devoted to the contributions of chemistry to lighting. A full report is reserved for our next issue. Likewise the New York section of the American Chemical Society did a very creditable and timely thing through the excellent report of its Chemical and Dyestuff Committee. We are glad to print this report in full in the present issue.

## Mexico

Nothing could be more hazardous than to predict the immediate political future of Mexico. It might be a pleasant pastime for as long as a day, but it would become wearisome to watch seriously the kaleidoscopic changes taking place in the southern republic. None but a keen and enthusiastic historian would care to chronicle and remember the unnumbered shifts of fortune. And yet peace and prosperity in Mexico are of the greatest immediate importance to the mining and metallurgical industry of the United States. Industrial and mining opportunities may and do exist in South America, but there are better known and proved opportunities nearer at hand in Mexico. Here is a rich field for the investor, the manufacturer of machinery and the operating engineer. To open it would be to relieve in a marked degree the depression here due to other causes, and bring prosperity to our own country as well as Mexico.

Under the domination of Villa, northern Mexico seems to be more nearly normal than any other part of the country; but even there the resumption of business is seriously handicapped by the disorganization due to several years of revolution. Shortage of labor is the most serious item. The native Mexican has never been noted for industry and close application to work, and several years of employment as a "soldier" have not improved his qualities as a laborer.

Nevertheless resumption of operations is proceeding at some mines and smelting plants. We are informed that the American Smelting & Refining Company is again operating a few furnaces at Chihuahua, Asarco, and Monterey. The majority of cyanide mills are still closed, although in some cases the companies are keeping superintendents on the ground ready to begin work when conditions warrant.

At the time of writing there is some hope of immediate settlement of political conditions in Mexico. We recall, however, that plans for peace must involve the self-effacement of contending leaders, and it is a question whether we may reasonably expect such evidence of patriotism. That virtuous quality has not been conspicuous among Mexican revolutionists; the "liberator" is very patriotic until he sees national power in his grasp.

## The Steel Trade's Prospects

Movements in the steel trade are traditionally difficult to forecast, and that this should be the case is readily understood when one reflects that the industry has rightly been called the barometer of general trade. How shall one undertake to forecast the movements of the barometer? One rather forecasts what the weather will be by observing what the barometer has done. The essence of the principle is that steel is the foundation of so many industries, entering into nearly all the operations of men, that as one industry after another prepares for activity it buys steel, and thus the various activities are focussed upon the one spot.

Between the date of production and the date of final ultimate consumption of steel a considerable interval must usually elapse, because for most uses steel undergoes somewhat elaborate processes of fabrication. As prices rise and fall buyers endeavor to take advantage of the fluctuations and thus the quantity of steel in progress from the rolling mill to the point of final consumption undergoes wide variations, wider than is generally recognized and running into the millions of tons. For instance, there have been times when steel cars were delivered to railroads before the traffic had grown sufficiently to require them, while at other times railroads have found themselves short of cars through a portion of their equipment proving unserviceable when suddenly called upon. By reason of this tendency of the quantity of steel in transit from the rolls to ultimate consumption to vary steel mill activity has fallen into a rhythm of long swings upwards and downwards. The experienced observer has frequently been able to determine what phase the wave was in at the moment, and thus prognosticate for the future.

It is said that all signs fail in dry weather and similarly all rules have fallen down in the face of the entirely new conditions brought about by the great war. Several times in the past fifteen years the steel industry has dropped to a rate of operating 50 per cent of capacity, and the attainment of such a low rate has been the signal that the rate was shortly to increase, but now the steel mills are operating at no more than about 35 per cent of capacity, a record low rate. The character of the movement, nevertheless, has been similar to that of movements in the past, in that the volume of material in transit from the mill to the point of final utilization has shrunk to very small proportions. Confidence in values of steel and confidence that banking accommodations will be afforded have always been the forces operating to arrest the decrease and produce an increase in this volume of material. Both these forces must now be present. Steel prices are as low as they were three years ago, in November, 1911, when they reached the lowest level since the establishment of the present order of things, the lowest since 1898. To secure orders of consequence, to "start a buying movement," the mills are doubtless ready in most cases to make some further concessions. As to financial accommodations, the new Federal Reserve system, put in practical operation Nov. 16, is believed on all hands to be adequate to meet the situation.

An increase in stocks of steel in transit can afford only temporary assistance to the trade. Actual consumption and utilization must increase, and for this the various industries consuming steel must become more prosperous. It has been a state of mind, rather than a set of physical conditions that has kept industries throttled in the past few months. There has been a period of panic, of unreasoning fear, and this condition must yield, is yielding now, we believe, to analysis and recognition that in a material way we are but little injured. The observation so commonly heard of late that the tremendous destruction of property occasioned by the war is an economic loss, and must be met, is not in point at this time. The settlement must come, but it will come later. The usual effects of war are fear and prostration first, next feverish and temporary recovery, producing a "boom" towards the close of and immediately after the war, and then still later a collapse and a long period of making up for the losses.

Some industries have found already that they are benefited by the war. Few are directly injured, though many have been forced to accommodate themselves to new conditions. The recovery of most industries will be less by development of concrete conditions in material things, than by changes in the mental state, and as the minds of men are much the same whether they make breakfast food, typewriters or overalls, the change will sweep over nearly all industries in much the same manner. The mental change will be relatively swift. The war itself fits men's minds for quick changes. The consumption of steel will then increase, not perhaps to the normal average, but to a much greater rate than that of the past month or two.

The greatest cloud in the sky has been the fear that American securities held abroad would be returned in such quantities that we could not settle the account. The war, however, puts affairs on the basis of material things, no money no credit. England, for instance, would require gold only to pay for materials, and those materials must be drawn largely from this country. American manufacturers have already sold millions and millions of dollars' worth of goods to the belligerent nations, the only definite knowledge of the identity of the real buyer being the fact that the direct purchaser was a man or firm prepared to pay spot cash in New York funds.

# Readers' Views and Comments

### Fire Brick

*To the Editor of Metallurgical & Chemical Engineering:*

Sir: Referring to the article in your August issue by Mr. J. E. Johnson, Jr., as well as to my criticism and his reply which appeared in your November issue, I would like to make a further comment.

In his article Mr. Johnson states, "In very recent years fire brick manufacturers began to make furnace bricks 3 inches thick," and in the same paragraph states, "They are, therefore, very much to be preferred from practically all points of view, except that of cost. In this respect the brick makers have established certain customs, which have not been permitted to any other trade." In the following paragraph in his article he gives the reason for their so doing as being "apparently on the ground that he needs it, and he usually succeeds in getting it." This is manifestly unfair to the fire brick manufacturer in its implication.

In answer to Mr. Johnson I wish to state that the increase in the cost to the consumer of a 3-inch brick over the cost of a 2½-inch brick is based solely upon the increase in cost in manufacture. As stated in my former remarks, a brick 9 x 4½ x 2½ in. is the standard and has been for many years, and a brick of this dimension is the most economical size to make from the manufacturers' standpoint. This statement can be verified by referring to the Refractories Manufacturers Association, which is an association of fire brick manufacturers producing about 75 per cent of the fire brick manufactured in this country.

Fully 75 per cent of the fire brick manufactured are fire brick of the 9-in. series and take a base price, which includes arch, key, wedge, soap, split, etc. The remaining 25 per cent are either larger or smaller than the standard 9-in. and are for special purposes. To make a fire brick larger than the standard requires more time in both the drying and the burning, which means a loss of plant capacity.

Second, the per piece loss in both drying and burning of what is known as the blast furnace brick is approximately the same as the per piece loss of brick in the 9-in. series. As a blast furnace square is more than equal to two 9-in. brick, the loss would, therefore, be double. This statement can be verified by any fire brick manufacturer with a cost accounting system that enters into these details, which answers Mr. Johnson's statement with the reason why the fire brick manufacturer "needs it" and why "he usually succeeds in getting it."

Referring to that part of his article in which he states in relation to this increased cost that "the brick makers have established certain customs which have not been permitted to any other trade," I refer Mr. Johnson to the catalog of any steel company. The one which I have before me is headed, "Standard Classification of Extras on Steel Bars and Shapes." Immediately under this heading is a table of rounds and squares, and I note that sizes from ¾ in. to 3 in. take a base price per 100 lb. (I believe the conservative base price is $1.25 per 100 lb.) A size ⅛ in. under the minimum carries an extra of 10 cents per 100 lb. or $2 per net ton, and 3/16 in. round or square carries an extra of $2 per 100 lb. or $40 per net ton.

Referring to those shapes larger than the shapes carrying a base price 3 1/16 in. to 3½ in., 15 cents extra per 100 lb. or $3 per net ton; 6⅝ in. to 7¼ in., $1.25 per 100 lb. extra or $25 per net ton extra. The extra which the fire brick manufacturer asks for a blast furnace shape, over his price for the standard 9 in., is less than 5 cents per 100 lb. or $1 per net ton.

From the foregoing comparison, entirely based on facts, Mr. Johnson is absolutely unwarranted in writing an article inferring that the fire brick manufacturer has a moral code that is in any way inferior to that of the steel manufacturer, and the idea suggests itself to me that the least Mr. Johnson can do is to retract his statement reflecting on the business ethics of the fire brick manufacturer.

Chas. S. Reed.

Chicago Retort & Fire Brick Co.,
Chicago, Ill.

* * *

*To the Editor of Metallurgical & Chemical Engineering:*

Sir:—Referring to Mr. Reed's second letter I do not see that these comparisons of utterly dissimilar matters get us anywhere. It would be easy to show that the ratio of sizes of steel bars from the smallest to the largest which take the base price is 16 to 1 while the ratio of the sizes of firebrick on which a stiff differential is charged is only two to one. Also that the weight of the individual bars makes handling much more difficult in the large sizes owing to this vast disproportion of weight, which is not the case to anything like the same extent with brick, and that the amount of bars over three inches which are sold is insignificant as compared with the amount between that size and three-quarter inch, while the number of large brick in a furnace lining is two-thirds that of the smaller size.

But to point this out only shows the futility of Mr. Reed's comparison. I have reason to believe, however, that there may be logical and tangible evidence that it costs more to make the large brick than it does to make the small ones, though I have hitherto been unable to obtain the reasons of this from the brick manufacturers.

If I succeed now in obtaining it, I shall take pleasure in either publishing it myself or getting some reliable brick manufacturer to do it, and if it justifies their claims I shall be more than willing to admit the fact and to revise my attitude on this question. If I have done brick makers an injustice they have only themselves to thank as they have been unable or unwilling to explain on grounds that seemed reasonable to me, and I believe to most furnace men, why they charged this differential. If Mr. Reed's letters have the (very indirect) effect of causing this information to be brought out, we shall all, brick manufacturers and furnace men alike, have reason to be grateful to him.

J. E. Johnson, Jr.

New York, N. Y.

### Accelerator for Gasoline Gas Plants

*To the Editor of Metallurgical & Chemical Engineering:*

Sir:—In your issue of June, 1914, there was an article on accelerators for gasoline gas plants by Mr. C. J. Barton.

The writer has had the same experience as Mr. Barton with poor gas in the winter time with the exception that on very cold days nothing but air with a faint odor of gasoline came through the pipes.

The generator is about 30 ft. or 40 ft. from the laboratory and the compressed air, which is furnished from the plant and controlled by means of reducing valves, bubbles through the gasoline in the tank. The pipe from the generator enters the building in the basement and goes up to the laboratory.

The accelerator, which is in the basement, consists of a rectangular 2-gal. tank. The pipe from the generator enters the accelerator at the bottom and the pipe to the laboratory is in the top. With this arrangement the lean gas enters at the bottom, bubbles through the gasoline and goes directly to the laboratory through the pipe in the top.

The accelerator is fitted with a stopcock in the bottom for drawing off the non-volatile liquid and a tight-fitting plug is screwed in the top for filling.

Not more than a gallon of gasoline is ever put into the accelerator and one filling will last for two days, except in very cold weather.

The furnace for heating the building is in another part of the basement and the accelerator is partitioned off with danger signs in conspicuous places.

H. P. KIMBER.

Bridgeton, N. J.

## Potatoes and Salt

*To the Editor of Metallurgical & Chemical Engineering:*

SIR:—It is related of a certain vine grower that, dissatisfied with the modest living afforded him by the product of his labor, he consulted an oracle of his day as to a possible improvement of his fortunes.

"Dig in your vineyard for gold," was the somewhat vague answer he received. So he dug. Naturally he took care not to injure the roots of his vines. The pot of money he expected to find never came to light, but the vines renovated by the unaccustomed tillage responded with such an increase of yield that they surpassed all records, and proved to be the source of the "gold" of which the eager peasant was in search.

"Thus, my children," said the sage, in concluding his great moral illustration, "we see how we may fail to secure pecuniary emoluments by the attempted entrainment of extraordinary elements, while close at hand is an environment which properly exploited will yield to us the objects of our efforts."

For a hundred years chemists laboriously sought for phosphorus in the urine, and produced it a few grains at a time, while all the time tons of bones were available. The only trouble was they didn't know that bones contained phosphorus.

How long had man sought for a preventive or cure for yellow fever, before the humble "stegomyia," otherwise "skeeter," was discovered to be the "carrier"? And afterward, all attempts to extirpate him by death having failed, how simple and close at hand the device by which, obviating the painful necessity of his death, we gently and mercifully prevented him from being born!

Long have we dreamed, earnestly have we worked at the problem of synthetic rubber. Now a murmur is heard that it has at last "arrived." Whether as a commercial rival to the native article may indeed still be, as Kipling puts it, "another story." Many are the means proposed, but among them none is more promising, certainly not one is more simple than the method suggested by our humble title.

Potatoes! The harmless necessary spud. Salt! Condiment alike of man and beast. World-wide each, and familiar in our mouths as household words, such are the domestic elements that have modernly combined to bring about the realization of one of chemistry's most seductive fancies, artificial caoutchouc.

Here, with some reluctance, we have to announce that we cannot give proper credit for parts of the alleged discovery, and have therefore decided to make no authoritative citations. In fact, the war now raging has stopped all communications with the countries most involved, and for the time being we have to content ourselves with such fragmentary information as had been developed at the time trouble began. We believe, however, that we are correct in distinguishing the three nationalities as below stated, as well as in the statement of the leading chemical principles involved.

Starting then with the potato, we risk no denial in saying that from it comes starch. From starch man has long since learned to produce alcohol, and from alcohol the jag. However, begging our reader's pardon, we wander a little from the subject. We do not have to get as far as the jag in any logical sequence having caoutchouc for its end.

The "alcohol" thus produced is, of course, our old friend ethyl alcohol $C_2H_5OH$. But one of the obstacles in the way of its production has always been the unwelcome presence of fusel oil, so called. This is well known to the chemist as amyl alcohol $C_5H_{11}OH$. Careful study of distillation methods has limited the percentage of the fusel oil obtained. Here comes the French contribution to the new discovery. Strictly speaking, this has no scientific bearing on the problem, for fusel oil has long been well known. However, the ingenious French chemist who is now in question seems to have reasoned thus: "If we know how to get a distillation with the minimum production of fusel oil, let us instead of trying to get rid of, multiply the conditions leading to its formation."

In short, the claim is said to be fairly established that the cost of fusel oil may now be reduced in the ratio of over three to one, roughly from about 30 cents a pound to 10 cents.

"But where does your rubber come in?" Patience, we haven't got to that yet.

We must now quit the hillsides of vine-covered France and cross the Rhine. Alas, it may be that the German chemist who is responsible for the next step in the synthesis has already fallen in the brunt of battle, and his French contemporary in the stress of strife. It may be that even the English discoverer to be presently brought in has been swept away, and this terrible war may have to its debit the loss of a great industrial discovery at the very crisis of its development. For, though the outlines have been fairly set forth, it has not been claimed that commercial competition had been yet approached, albeit some of the product had been actually tested even in auto tires and had been pronounced excellent.

Our information as to the next step is scanty. This much is known, viz., that iso-amyl chloride (itself, of course, formed by the action of some chloride on the amyl alcohol) is first produced. Isoprene, the next objective point in the synthesis, has been produced from amyl alcohol. The broad statement that it is produced by the "action of chlorine" hardly satisfies the chemist's longing for technical detail. It is quite possible that some further operative detail has appeared which has escaped our attention, as we have not access to every current source of chemical information.

Isoprene is credited with the formula $C_5H_8$. Rubber has always been written as its polymer, $C_{10}H_{16}$. As usual, there was no great difficulty in getting rubber to dissociate into isoprene. There was difficulty amounting to impossibility in getting isoprene to build itself by internal molecular union into rubber!

Parenthetically, we may say that it is easy enough to represent various reactions by equations, without deriving much practical knowledge from the latter. A multitude of equations represent merely the initial and final stages of some transformation. We do not attempt here to "equate." Furthermore, we are well aware that other methods of obtaining isoprene have been published. As they do not fit into this scheme they are passed by.

Isoprene, it is claimed, has been transformed into rubber by methods which include a time element so great as to be fatal to commercial success. The latest discovery, however, eliminating the time factor as is claimed, comes from England. This has become familiar, but as we have started out to make this sketch impersonal, we can hardly violate the rule in any one case. The discovery was made as follows: Isoprene is difficult to dry, some water being so intimately intermixed or combined that it cannot be driven out by heat without decomposition of the main body. In seeking to remove the last of this water, metallic sodium was employed.

A wire of the metal was laid in a test tube filled with the liquid isoprene, the tube being corked. A remarkable catalysis developed. The isoprene polymerized into rubber!

But how does it accomplish this? It may be seriously doubted whether anyone is competent to explain mysterious reactions of this kind. The modern school regards molecules as very heavy artillery, quite unfit to open an action. But when it comes to catalysis (recently a reaction has been cited where one part in seventy millions effected the transformation), then, like Richard II, we do indeed "stand amazed." Our chemical equations seem as much out of place as catapults on a modern battlefield.

But our title is justified. Let us briefly review the steps of this synthesis.

We need not be particularly scientific or even technical to be understood.

CHAPTER I

*Potatoes.* Starch. Fusel oil. The latter more cheaply obtained than hitherto.

CHAPTER II

Fusel oil. Iso-amyl chloride. Isoprene.

*Chlorine* the essential element in this part of the evolution.

CHAPTER III

*Sodium* the efficient agent for transforming isoprene into caoutchouc.

CHAPTER IV

Chlorine and sodium form common salt. More correctly, sodium and chlorine are derived from salt.

Potatoes furnish the material. Salt furnishes the two active agencies.

Why then search air, ocean, and earth for something "new and strange" when we can find the elements for our most startling synthesis in that humblest meal of the lowly: "Potatoes and salt."

Regis Chauvenet.

Denver, Colorado.

### Cyanide Practice in the Porcupine District

*To the Editor of Metallurgical & Chemical Engineering:*

Sir:—I note Mr. Parmelee states in your November issue that in his article on cyaniding in the Porcupine district in the October number he had credited Dorr classifiers to the McIntyre Mill and Colbath classifiers to the Dome, whereas it should have been the reverse.

To bring the description up to date and in the interest of accuracy you may care to state that the McIntyre mill has replaced the Colbath with a Dorr classifier and has just ordered an additional one to handle their increase in capacity.

This exemplifies the difficulty of having a description correct when it is published, for Mr. Parmelee's article was probably based on his visit made last June.

H. N. Spicer.

Dorr Cyanide Machinery Co., New York City

## The Iron and Steel Market

November has been the poorest month the steel trade of the United States ever experienced. Actual purchases of steel have not equalled 25 per cent of the productive capacity, while actual production dropped from a rate of about 40 per cent of capacity at the beginning of the month to a rate of less than 35 per cent at the close.

These conditions have never before been paralleled in history.

The reduction of stocks in the hands of jobbers and manufacturing consumers has been unparalleled, the influences being a distrust of values, as steel prices were constantly falling, a doubt whether material would be needed at all in the near future, the war inducing a panic preventing judgment from being exercised, and difficulty in carrying material by reason of the almost complete lack of banking accommodations.

The war has affected the minds of men much more than it has affected material things. It did not prevent the crops maturing and it is not now greatly affecting the importation and exportation of merchandise. The collective mind has passed through many stages. Upon the announcement of war there was a sudden fright, followed by a view that prices would advance and many materials become scarce, this resulting, about the middle of August, in some price advances in steel and a small-sized buying movement. Later, with a full realization of the horrors of war and the complete dislocation of trade promised there succeeded a period of panic, of unreasoning fear, which resulted in constantly decreasing buying, up to the beginning of November, when the irreducible minimum appears to have been reached at last. Since the beginning of November the mental attitude has greatly improved. Almost everywhere a more cheerful feeling is to be observed and the greatest barrier to a recovery in trade has been removed.

Steel prices continued to fall throughout November, until at the close of the month the average level was as low as three years earlier, when the lowest point was reached since 1898. The burden upon steel manufacturers is vastly greater now than then, for wages are higher, through the general advance of early in 1913, and the cost of production is also increased by the lowness of the rate of operation, not over 35 per cent of capacity, against about 75 per cent in November, 1911.

Many steel interests have not been earning their fixed charges.

The decline in activity and prices seems now to have run its course. A mild improvement in buying is to be expected for December, and after the turn of the year more rapid progress is likely to be made. In many quarters it is believed that in April the mills will be operating at double the present rate, though few expect full operation in the industry before the close of the war.

Export trade in iron and steel has been increasing, but is still relatively light. South America was formerly our best country, but is now prostrated. The exports now being made are largely along a new line of trade, involving in large part war materials to countries that hitherto have not bought iron and steel from us in any large quantity. Barb wire, lathes, steel rounds for shrapnel, light rails with ties for portable railway, are examples of such material. Iron and steel exports in December promise to exceed 100,000 tons, against an average of 140,000 tons a year in the first six months of this year, 114,000 tons in July, 86,000 tons in August and 96,000 tons in September.

### Pig Iron

While November showed no material increase in steel buying, there was a distinct increase in pig iron buying. The Buffalo district reports large sales of foundry iron, while in the valleys and the St. Louis districts there have been fairly large purchases of basic iron by steel foundries, though practically none by steel rolling mills. Pig iron prices declined slightly about the beginning of November, but afterwards became practically stationary, at the lowest level since 1904. The rate of production, after a long decrease, appears to be approximately stationary.

The market is quotable as follows: No. 2 foundry, Birmingham, $10; delivered Philadelphia, $14.45; f.o.b. furnace, Buffalo, $12; f.o.b. furnace, Chicago, $12.50; at valley furnaces (95 cents delivered, Pittsburgh, by the recent five-cent freight advance): Bessemer, $13.75; basic, $12.50; No. 2 foundry and malleable, $12.75 to $13; gray forge, $12.50 to $12.75. England has placed conditional embargoes on manganese ore exports from India and ferromanganese exports from England, but consumption is so light that the market has not been disturbed, there being large stocks. The nominal price is $68, Baltimore.

### Steel

The market for unfinished steel has weakened even though there has been no serious enquiry to tempt reductions. It is well established that for early delivery at least billets can be had at $19 and sheet bars at $19.50, f.o.b. maker's mill, Pittsburgh or Youngstown, rods being $25, Pittsburgh. On prompt lots these prices could probably be shaded, but on the other hand it is not certain that contracts could be made at such figure for first quarter.

### Finished Steel

During the month bars, plates and shapes declined about $1 a ton, iron bars dropped irregularly and black and galvanized sheets declined $1 a ton. On November 1 the extra 2½ per cent discount to jobbers in steel pipe was removed, while the basing discount was increased one point, effecting a net reduction of about $1 a ton.

Current prices as closely as can be quoted are as follows, f.o.b., Pittsburgh, unless otherwise noted. In the Chicago district and in the east many products are sold at delivered prices equivalent to less than the Pittsburgh base prices here quoted.

Rails, standard sections, 1.25c. for Bessemer, 1.34c. for open-hearth, f.o.b. mill, except Colorado.

Plates, tank quality, 1.05c. to 1.10c.

Shapes, 1.10c.

Steel bars and bands, 1.10c.; hoops, 1.25c.

Refined iron bars, 1.20c., Pittsburgh; common iron bars, 1.10c., Philadelphia; 0.95c., Chicago.

Sheets, blue annealed, 10 gage, 1.40c.; black, 28 gage, 1.85c.; galvanized, 28 gage, 2.85c.; painted corrugated, 28 gage, 2.05c.; galvanized currugated, 28 gage, 2.90c.

Steel pipe, ¾ to 3-in., 81 per cent off list.

Standard railroad spikes, 1.35c., Pittsburgh; 1.45c., Chicago.

Structural rivets, 1.45c.; boiler rivets, 1.55c.

Cold-rolled shafting, 67 per cent off list.

Chain, ⅜-in. proof coil, 3.00c.

---

**Gas-Engine Driven Compressors.**—The C. & G. Cooper Company, of Mount Vernon, Ohio, are supplying a 950-hp twin tandem gas engine to the Medina Gas & Fuel Company for the Mansfield, Ohio, station. This will be the third Cooper unit in the plant. The Ohio Fuel Supply Company have also ordered three 475-hp single tandem gas-engine driven compressors.

## The Western Metallurgical Field

### Cyanide Consumption in the United States and Canada

For some months past there has been considerable speculation as to the quantity of sodium and potassium cyanides consumed in the metallurgical industry in the United States and Canada. Various estimates have been given, based on the tonnage of ore treated and the probable average consumption per ton of ore, but no wholly satisfactory figures have been published.

Fortunately the United States Geological Survey began in 1911 to include in its statistics on gold and silver production, the consumption of sodium and potassium cyanides, and has continued that commendable policy through 1912 and 1913. Excepting California and Oregon, data are complete for all states in which cyaniding is practiced even as a minor metallurgical process. The two states mentioned are not large consumers of cyanide, as amalgamation and smelting probably account for the recovery of the major portion of their total production of precious metals. Cyanidation is gaining a foothold in these states, but the quantity of cyanide consumed would not greatly affect the total for all states.

Neglecting definite figures for California and Oregon, and combining the figures for Texas and Wyoming with those for New Mexico and South Dakota, respectively, we believe the following table compiled from United States Geological Survey statistics, gives the most complete and reliable data yet published.

| State | 1911 Pounds | 1912 Pounds | 1913 Pounds |
|---|---|---|---|
| Arizona | 115,877 | 129,987 | 189,291 |
| Colorado | 759,149 | 837,537 | 919,963 |
| Idaho | 181,808 | 161,156 | 94,475 |
| Montana | 91,657 | 93,344 | 116,422 |
| Nevada | 2,352,961 | 2,618,424 | 2,798,224 |
| New Mexico | 165,396 | 147,035 | 207,605 |
| South Dakota | 599,845 | 580,231 | 505,142 |
| Utah | 205,041 | 203,721 | 70,238 |
| Washington | 9,700 | 36,517 | 32,090 |
| | 4,481,434 | 4,807,952 | 4,933,450 |

New Mexico for 1913 includes small quantity from Texas.

South Dakota for 1912 and 1913 includes small quantity from Wyoming.

With California and Oregon added, the grand total for 1913 would be, roundly, 5,000,000 lb. The figures given show increased consumption of 7 per cent in 1912 over 1911, and 2.6 per cent in 1913 over 1912. From 1911 to 1913 the consumption increased roundly 10 per cent. It seems likely that these figures are accurate, for while other statistical data gathered from operators may be subject to error through estimates, it is likely that individual consumers can ascertain with considerable certainty how much cyanide they purchase and use. It is to be hoped that the Geological Survey will extend this useful work in California and Oregon, so that we may know accurately how much cyanide is consumed in the treatment of precious-metal ores.

The consumption in Canada is clearly set forth in a communication from Mr. J. McLeish, chief of the statistical division of the mines branch, Department of Mines, Ottawa, as follows:

"Direct returns have not been received from Canadian mining companies with respect to their consumption of cyanide, but in view of the fact that there is no local production, a fairly accurate estimate of the consumption in Canada will be furnished by the record of imports, a detailed statement of which is attached hereto.

"The imports of all cyanides for metallurgical purposes in 1911 totaled 308 tons, or an average of about 25 tons per month. The imports in 1912 totalled 475 tons, or an average of nearly 40 tons per month. The imports in 1913 totalled 708 tons, or an average of 59 tons per month. During the first six months of 1914 the imports totalled 227 tons, or an average of only 38 tons per month, but in the month of August the imports increased to 130 tons. These figures should represent approximately the Canadian consumption of cyanide."

Imports into Canada of Cyanide of Potassium, Cyanide of Sodium, and Cyanogen Bromide for Reducing Metals in Mining Operations.

| 1913 | Pounds | Value |
|---|---|---|
| January | 84,512 | $12,648 |
| February | 10,407 | 1,192 |
| March | 160,134 | 24,174 |
| April | 77,170 | 11,566 |
| May | 80,415 | 12,235 |
| June | 178,025 | 28,197 |
| July | 71,267 | 13,784 |
| August | 183,498 | 27,802 |
| September | 89,806 | 13,556 |
| October | 208,966 | 31,559 |
| November | 142,099 | 21,026 |
| December | 129,370 | 19,433 |
| Total | 1,415,669 | $217,472 |
| **1914** | | |
| January | 177,392 | $25,363 |
| February | 134,413 | 19,270 |
| March | 143,069 | 20,116 |
| April | 82,954 | 11,540 |
| May | 193,241 | 28,113 |
| June | 96,757 | 14,038 |
| July | 96,377 | 13,333 |
| Total 6 months | 454,874 | $64,749 |
| August | 260,799 | $46,513 |
| Total for 1911 | 615,607 | $94,397 |
| Total for 1912 | 950,238 | $143,978 |

Of the gold and silver producing districts of Canada, Cobalt and Porcupine are by far the most important. According to figures compiled by Mr. A. A. Cole, mining engineer for the Temiskaming & Northern Ontario Railway Commission, Cobalt is consuming about 50 tons of cyanide per month and Porcupine about 20 tons. Mr. Cole has communicated this and other information to the Canadian Mining Institute, from the November *Bulletin* of which we taken the following notes: On the outbreak of the war it was found that with one exception all the northern Ontario mining companies were getting their cyanide from the Cassell Cyanide Company, Ltd., of Glasgow, Scotland. To this company the British government suggested the policy which is now being followed with respect to sales of cyanide, viz., to sell none of this chemical outside the British Empire until first the gold and then the silver mines within the empire have been supplied. The Cassell company is now making additions to plant, but it will be some months before increased output can be made. The price of cyanide in Ontario is now 18 cents per pound, having risen 3 cents per pound since the opening of the war. The Cassell company is now offering, however, to supply the mines with cyanide for the next two years at 18 cents per pound, and at 16 cents during 1916, providing the mines will agree to buy all their cyanide from this company alone during that time. It appears now from Mr. Cole's estimates that within a year the consumption in northern Ontario will be at the rate of 100 tons per month, or 2,400,000 lb. per year, which is almost half the 1913 consumption in the United States.

### Determining Percentage of Gold in Quartz

In a discussion before the Teknik Club, of Denver, on the subject of determining the percentage by weight of gold in a specimen of free gold in quartz, it was pointed out that at least half a dozen formulas have been published for the solution of the problem. Some of these formulas are obviously incorrect; others are of doubtful value, as their derivation is obscure. The simplest form of correct formula for solving this problem requires only a knowledge of the specific gravities of the constituents and the specimens. It is assumed, of course, that the specimen consists of practically pure constituents. If we let

$G_1$ = sp. gr. of the specimen,
$G_2$ = sp. gr. of gold, and
$G_3$ = sp. gr. of quartz.

then the percentage of gold in the specimen can be determined from the following formula:

$$x = \frac{100G_2(G_1 - G_3)}{G_1(G_2 - G_3)} \qquad (1)$$

If, for example, we have a specimen of sp. gr. 5, and take the sp. gr. of gold as 20, and of quartz as 2.5, then

$$x = \frac{100 \times 20(5 - 2.5)}{5(20 - 2.5)} = 57.1 \text{ per cent gold in specimen.}$$

If a simple arithmetical proof is required, it can be given as follows: Under the conditions assumed

| | |
|---|---|
| 1 cc gold weighs | 20 g. |
| 6 cc quartz weighs | 15 g. |
| 7 cc specimen weighs | 35 g. |

$$\text{Sp. gr. of specimen then} = \frac{35}{7} = 5$$

$$\text{Percentage of gold} = \frac{20}{35} = 57.1.$$

Another formula which has been wrongly supposed to give the solution of this problem is

$$x = \frac{100(G_1 - G_3)}{G_2 - G_3} \qquad (2)$$

Applying this formula to the problem assumed above we get 14.3 per cent, an incorrect answer. As a matter of fact, 14.3 represents the percentage by *volume* of gold in the specimen (being one-seventh, as shown above), and the percentage by weight can be calculated from the volumes and specific gravities of the constituents.

Formula (2), however, is correct for obtaining the percentage by weight of a concentrate obtained from treatment of a simple ore consisting of one mineral and gangue, when assays of ore, concentrate and tailing are known, letting

$G_1$ = Head assay,
$G_2$ = Concentrate assay, and
$G_3$ = Tailing assay.

Still another application of formula (1) is in the determination of the per cent of solids in, say a cyanide pulp, where

$G_1$ = Sp. gr. of the pulp,
$G_2$ = Sp. gr. of the dry solid, and
$G_3$ = Sp. gr. of water, or 1.

The formula then becomes

$$x = \frac{100G_2(G_1 - 1)}{G_1(G_2 - 1)}$$

### Company Reports

**Camp Bird Limited** has issued an annual report for the year ended June 30, 1914. A grave crisis in the company's affairs arose during the year due to the failure of the Canadian Agency, Ltd., Messrs. Chaplin, Milne, Grenfell & Company and Mr. A. M. Grenfell. Changes in the administration of the company since that time have resulted in economies amounting to between $9,000 and $10,000 per annum. Mr. R. J. Frecheville resigned as a director and was made chairman of the technical committee, which has charge of the company's mines. The other members of the committee are Messrs. J. A. Agnew and L. Chevrillon. In regard to the Camp Bird mine, the statement is made "that the development work in the bottom of the mine has not shown any considerable addition to the ore-reserves." In the Santa Gertrudis mine, development on the main vein at the lowest levels has not been encouraging, but on the other hand some very encouraging ore-bodies parallel to the main vein have been discovered. Ore reserves at June 30 were estimated at 1,194,000 tons. The Messina (Transvaal) Development Co., Ltd., was plunged into severe difficulties by the financial failures referred to, but is expected to solve its own financial difficulties. The estimated ore reserves developed to the ninth level are 247,000 tons of 9 per cent copper ore. The mine and plant are in first-class condition. With respect to the Central American Goldfields Syndicate, Ltd., difficulties have arisen over title to property and litigation is imminent. Operations have been suspended for the present.

The Camp Bird mill treated 30,595 tons of ore during the year, yielding an average of $26.19, as against $22.51 in the year previous. The extraction was 94 per cent. Of the total extraction, 52.97 per cent was by amalgamation, 42.07 per cent by concentration and 4.96 per cent by cyanidation. The value of the ore treated was distributed as follows: gold, 87.49 per cent; silver, 9.01 per cent; lead, 1.67 per cent; copper, 1.83 per cent. The metal content of the ore was as follows: gold, 1.135 oz. per ton; silver, 4.27 oz. per ton; lead, 1.324 per cent; copper, 0.260 per cent. The gross value recovered in the stamp mill was $761,330; net recovery, $710,234. The cyanide mill recovered $39,748 gross, or $12,379 net. Total net recovery, $722,603.

At the Santa Gertrudis property the Guadalupe mill remained closed. During the year 233 flasks of quicksilver were recovered from the old patio. The new mill was in operation until the 21st of April, when the American occupation of Vera Cruz caused a suspension of transportation facilities and an exodus of the foreign staff. The plant remained idle during the balance of the year, but was opened again on July 6, 1914. The crushing rate was 28,660 tons in July, 1913, 32,849 tons in March, 1914, and is now about 20,000 tons per month.

The quarterly report of the **Ray Consolidated Copper Co.** for the third quarter of 1914, shows an average monthly production of copper in concentrates of 4,158,384 pounds, as against an average of 6,249,448 pounds per month during the preceding quarter. Ores shipped direct to smelters contained 161,032 pounds of copper, bringing up the total production for the quarter to 12,636,185 pounds. A 50-per cent reduction in output was inaugurated August 5, due to the European war. The ore treated during the quarter averaged 1.691 per cent copper. The recovery was 67.47 per cent. The milling cost was 45.85 cents, compared with 47.24 cents for the second quarter and 53.15 cents for the first. The average mining and coarse crushing cost was 57.681 cents per ton, of which 2.814 cents was for coarse crushing. This is a reduction of 7 cents compared with the preceding quarter. The average cost of copper, after allowing for smelter losses and applying the dividends from the Ray & Gila Valley Railroad, but no other miscellaneous income as a credit to costs, was 8.849 cents per pound. If all miscellaneous incomes were credited as a reduction of cost the figure would be 8.738 cents per pound. Low costs are being maintained in spite of reduction in capacity. At both mine and mill men have been employed on alternate days in order to provide employment for the largest number and to maintain the operating organization.

**The Utah Copper Company's** report for the third quarter of 1914 shows a marked decrease in tonnage of ore treated and copper produced. The average monthly production for the quarter was 9,562,224 pounds of copper. The September production was only 6,672,194. The tonnage treated was 1,466,606 tons as compared with 2,006,157 tons for the preceding quarter. The Magna plant milled 77 per cent and the Arthur 23 per cent. Since August 7 the Arthur plant has been closed. The average grade of ore milled was 1.4356 per cent; the average extraction was 68.13 per cent. The cost per pound of copper produced was 7.76 cents, as compared with 7.539 cents in the previous quarter. Crediting miscellaneous income, the cost per pound of copper is 6.951 cents.

**The Nevada Consolidated Copper Company** shows in its third quarterly report for 1914 the same conditions of curtailment of production as indicated above for the other copper producers. The average monthly production for the third quarter was 3,752,807 pounds of copper, the output in September being 2,718,471 pounds. The output in March was 5,218,227 pounds. During the quarter 599,126 tons of ore was milled, averaging 1.52 per cent copper. In addition to this tonnage, the company also milled 11,322 tons of Giroux ore. The cost per pound of copper after crediting miscellaneous income was 9.59 cents, as compared with 10.73 cents for the previous quarter.

The reduced cost is due to the higher grade of ore treated.

The report of the **Chino Copper Co.** for the third quarter of 1914 shows a gross production of copper in concentrates of 11,491,120 pounds, as compared with 17,032,871 pounds in the preceding quarter. The September production was 3,237,869 pounds, compared with 6,109,888 pounds in April. Besides copper in concentrates there was produced in direct smelting ore 286,693 pounds of copper. The total tonnage of ore treated was 390,000, the average grade being 2,165 per cent copper. Average extraction was 68.04 per cent. The concentrates averaged 16.79 per cent copper. The cost per pound of net copper produced from milling operations, without allowing credits from miscellaneous income, was 7.81 cents. During this quarter, for the first time since the beginning of operations, the quantity of gold in concentrates was sufficient to receive consideration from the smelter. The net credit from this source amounted to 0.10 cents per pound of copper. Crediting all miscellaneous income, the cost per pound was 7.37 cents. The cost of operations is being maintained at a low figure in spite of curtailment of output; thus the cost for September, on half capacity, was 6.65 cents per pound of copper produced, without crediting miscellaneous income. The new primary crushing plant has been put in operation at the mine and has been of assistance in increasing efficiency.

## The Non-Ferrous Metal Market

Toward the end of November a distinct improvement was noted in the metal market. Prices for lead, copper and spelter advanced and more business was transacted. The London metal exchange opened on November 9. Export of copper has been affected by the British government in detaining copper shipments with the idea of preventing them from reaching a possible market in Germany. The action has caused loud protests from American copper producers, and our government has been urged to take steps to maintain such foreign market as exists.

**Copper.**—Business has been more brisk and domestic demand is good, especially among Connecticut consumers in the brass industry. Prices have been rising from 11 cents to nearly 12. The latest available quotation is about 11.87½ cents, New York.

**Lead.**—Good business has been done both in New York and St. Louis. The metal is quoted at 3.60@3.62½ cents, St. Louis, and 3.65@3.75 cents, New York.

**Tin.**—This market has been strong for immediate delivery. Spot supplies are apparently scarce and futures not in demand. The market has been active at about 34¼ cents, New York.

**Spelter.**—This metal was one of the last to share in the general market improvement, but demand has increased and prices have risen to 4.95@5.00 cents, St. Louis, and 5.10@5.15 cents, New York.

**Other Metals.**—The aluminum market continues without feature, and quotations are unchanged at 18 @18.5 cents, New York. Prices for various brands of antimony range from 12 to 18 cents, New York, with comparatively small stocks of metal available. The quicksilver market has fallen since our last report, importations from Europe having added to the supply. Flasks of 75 lb. are sold at varying prices, averaging about $43, though a wider range in bid and ask prices.

## Obituary

**William Lofland Dudley** died on September 8, 1914, en route from Clifton Springs Sanitarium to his home in Nashville, Tenn., after a sudden stroke of paralysis. He was born on April 16, 1859, in Covington, Ky., and educated in the public schools of Covington and the University of Cincinnati, from which he graduated as B.S. in 1880. (The same institution conferred on him last year the degree of Doctor of Laws.) At the University of Cincinnati he studied with F. W. Clarke, then professor of physics and chemistry. He was then demonstrator of chemistry, and after a year professor of chemistry and toxicology at the Miami Medical College of Cincinnati, which conferred on him the honorary degree of Doctor of Medicine. In 1887 he accepted the professorship of chemistry at the Vanderbilt University in Nashville, Tenn., where the main work of his life was done, until poor health forced him to retire from active work two years ago. He carried out a very large amount of chemical research leading into the most varied fields of chemical science. But he was a much bigger and broader man than a mere chemist. He was fond of art, especially music and literature, active in civic affairs, and loved clean sport. He organized the Southern Intercollegiate Athletic Association, and the athletic field at Vanderbilt University is called Dudley field. After his friend Dr. Kirkland became chancellor of Vanderbilt University, Dr. Dudley became dean of the medical school and thoroughly built it up. He never married.

* * *

**Frederick Augustus Heinze**, who for many years was a spectacular figure in the mining industry, particularly in Butte, Mont., died at Saratoga Springs, N. Y., November 4, at the age of forty-five. As a young engineering graduate of the Columbia School of Mines in 1889, Mr. Heinze went to Butte, where he subsequently founded the Montana Ore Purchasing Co. and established a profitable smelting industry. This venture was based on his firm belief that a smelting business in that district could be made a profitable business and it was the foundation of the fortune which he afterward accumulated. During his career he was involved in litigation almost constantly with the large companies of Butte, and the political history of Montana at that time gives evidence of the extent to which agencies of all kinds were involved in suits and controversies. In 1902 Heinze consolidated his interests in the United Copper Co., and about four years later the fight between him and the Amalgamated Copper Co. was terminated by the sale of his properties to this concern. After this he went to New York City and engaged in several financial ventures, establishing the Stock Exchange firm of Otto C. Heinze & Co., and purchasing control of the Mercantile National Bank. High finance was apparently breaking right for Mr. Heinze when, in 1907 his various financial houses failed and he was ousted from the presidency of the Mercantile National Bank. From the wreck of his various mining and financial ventures he saved mainly the Stewart mine in Idaho and the Mascotte tunnel in Utah.

Mr. Heinze was married in 1910 to Mrs. Bernice G. Henderson, who died within about two years. A son, F. Augustus Heinze, Jr., survives.

* * *

**David J. Kelly**, of Salt Lake City, died at his home on October 10, 1914, aged 37 years. He was a native of Utah and an engineering graduate of the University of Utah, receiving the mining engineer's degree. He was identified with various phases of the mining industry, having been assayer for the Salt Lake branch of the Kansas City Consolidated Smelting & Refining Co., and later with George Moore at Sunshine, Utah. Mr. Kelly became widely known in the metallurgical industry through his invention and development of the Kelly filter press, which finally attained prominence and success after a number of years of financial and mechanical difficulties. He is survived by a widow and two sons.

* * *

**Douglas S. Martin**, who relinquished his position on the editorial staff of the *Electrical World* in August to enroll in the forces of Great Britain, has succumbed to shrapnel wounds received at the battle of Messines on the Belgium border. Mr. Martin was graduated as an electrical engineer from the Central Technical College, London, England, and was formerly editor of the *General Electric Review*. After resigning from that paper he engaged in electrical work in the Far West, and on returning East joined the editorial staff of the *Electrical World*. Mr. Martin was twenty-seven years of age. He was a brother of Mr. T. C. Martin, secretary of the National Electric Light Association.

## International Engineering Congress

A report having been recently circulated to the effect that the International Engineering Congress, San Francisco, 1915, would be abandoned, the officers of the Congress have announced that the rumor is incorrect and that the Congress will be held as scheduled, September 20 to 25, 1915.

In view of the conditions now prevailing in Europe, the governing bodies of the five National Societies under whose auspices the Congress is to be held, have recently given careful consideration to the feasibility of holding the Congress and to the probability of its success, with the result that each body has unanimously confirmed its original pledge to support the Congress. The Committee of Management is actively proceeding with arrangements, which are now well advanced, for meetings on the scheduled dates and for the publication of the transactions.

The Committee of Management is in receipt of a sufficient number of communications from various foreign countries throughout the world, including those located within the war zone, to indicate that a large majority of the papers originally requested for presentation at the sessions of the Congress and publication in its transactions will be handed in on time, and that the Congress will be truly international in character.

**Fuel Oil.**—We have received from Messrs. Tate, Jones & Company, Inc., of Pittsburgh, Pa., their recent illustrated bulletin on Appliances for Burning Fuel Oil. After an introduction on the economies of oil as fuel and on actual results obtained with oil for steam raising and in furnace work, the first main part of the bulletin deals with standard oil burner designs, because success with oil fuel depends upon the burner. The second part describes systems for pumping, heating and regulating oil flow at burners.

# The Heat Balance of the Blast Furnace

BY SIDNEY CORNELL

Much has been written in relation to the modern blast furnace, and articles dealing with blowing in, furnace practice, and the effect of this and that condition on the furnace working are commonly seen in various papers.

Constant and systematic records are kept in most blast furnace plants of blast temperature, amount of free air blown, analysis of materials, the products of the furnace, etc., but these records seem to be for use when trouble occurs. A heat balance is useful and instructive, and can usually be figured from the data obtainable from the permanent records.

The following data was collected from a well-known plant of six 600-ton blast furnaces and average figures taken to effect the heat balance.

Table No. 1 contains the data of materials charged, together with material made, cooling water used, etc., and is arranged under the four headings: Tons per day, pounds per ton of pig iron made, tons per charge, and pounds per charge. A furnace making 445 tons of pig iron per day has sixty-four charges charged per day, which makes a period of 22½ minutes per charge. Accordingly a test period of 22½ minutes is taken and the heat balance figured accordingly.

TABLE No. 1

| | Tons per day | Pounds per ton pig | Tons per charge | Pounds per charge |
|---|---|---|---|---|
| Group No. 3 | 457 | 2,302 | 7.14 | 16,000 |
| Group No. 4 | 174 | 878 | 2.72 | 6,100 |
| Group No. 7 | 113 | 575 | 1.78 | 4,000 |
| Buffalo | 100 | 503 | 1.56 | 3,500 |
| Open hearth cinder | 57 | 287 | .89 | 2,000 |
| Flue dust charged | 20 | 100 | .31 | 700 |
| Roll scale | 20 | 100 | .31 | 700 |
| Flue dust loss | 45.5 | 230 | .71 | 1,600 |
| Coke charged | 457 | 2,302 | 7.14 | 16,000 |
| Coke breeze in yard | 7 | 34 | .11 | 240 |
| Total coke | 464 | 2,336 | 7.25 | 16,240 |
| Limestone | 205 | 1,036 | 3.21 | 7,200 |
| | (Cubic feet) | | | |
| Wind @ 90° F. cf | 42,188 | ...... | ...... | ...... |
| Pig iron made | 446.28 | 2,247 | 6.97 | 15,620 |
| Runner scrap | 1.28 | 7 | .02 | 50 |
| True pig iron | 445 | 2,240 | 6.95 | 15,570 |
| | Gallons | | | |
| Cooling water | 2,571,240 | 47,960 | 148.70 | 333,350 |
| True slag | 267 | 1,344 | 4.17 | 9,340 |

In the figuring of a heat balance two conditions present themselves, viz., whether the blast furnace gas is cleaned before using or not, and whether the blowing engines are steam operated or gas driven. In the case of gas-driven blowing engines the gas must be cleaned, and further it is reasonably certain that cleaned gas gives better efficiency in the blast furnace stoves and boilers. In the plant where this data was collected both conditions were available and accordingly the necessary data was obtained.

Table No. 2 contains miscellaneous data necessary in figuring the heat balance, temperature, etc., and Table No. 3 the analysis of materials charged and produced.

On account of the numerous chemical reactions involved it is necessary to compile an "elementary distribution" with the object in view of their final arrangement in the metal, slag, and gases. Taking each of the materials charged, their weight, and analysis, the Table No. 4 is obtained. Taking the silicon reduced from silica, the manganese reduced from the oxide, phosphorus, and sulphur, we get the arrangement in the metal, and the arrangement of the other substances in the slag and gases.

The starting point in the calculations is the hot blast, and in this test 32 deg. Fahr. is taken as the base point.

TABLE No. 2

TABLE OF MISCELLANEOUS TEMPERATURES AND OTHER DATA REQUIRED FOR THE HEAT BALANCE

| | |
|---|---|
| Tonnage of basic iron per day | 445 tons |
| Number of charges per day (average) | 64 |
| Temperature of air in blowing room | 90° F. |
| Temperature of air at snort valve | 200° F. |
| Temperature of hot blast on clean gas | 1210° F. |
| Temperature of hot blast on dirty gas | 1110° F. |
| Temperature of furnace top | 425° F. |
| Temperature of B. F. gas at stove burner, dirty gas | 280° F. |
| Temperature of B. F. gas at stove burner, clean gas | 90° F. |
| Cu. ft. free air blown per minute, test | 42,188 cu. ft., at 90° |
| Pounds of air blown during test | 68,000 |
| Hot blast pressure | 15.7 pounds |
| Cooling water used, for 24 hours = | 2,571,000 gallons |
| Average temperature difference in cooling water = | 8° F. |

## Hot Blast

HOT BLAST. AIR IN ENGINE ROOM AND STOVES

A. Air in Blowing Room.

| | # | T° | Range | | SM(o-t) | B.t.u. |

## Heat Generated and Absorbed

D. Heat in Materials Charged.

| Dry Material | # | T° | Range | SM | B.t.u. |
|---|---|---|---|---|---|
| Mixed ores | 28,946 | 70 | 38 | 0.14959 | 164,529 |
| Coke | 15,632 | 70 | 38 | 0.24100 | 143,157 |
| Limestone | 7,092 | 70 | 38 | 0.20860 | 56,217 |
| Water in above | 4,530 | 70 | 38 | 1.00000 | 172,140 |
| Total | | | | | 536,043 |

From the "elementary distribution" we get the carbon actually burned and as follows:

| | | |
|---|---|---|
| Carbon in flue dust charged | 63.0 | .... |
| Carbon in coke charged | 13770.0 | .. |
| Carbon absorbed by pig iron | ..... | 533.0 |
| Carbon in flue dust made | ... | 160.0 |
| Total | 13833.0 | 693 0 |
| Carbon burned | 13139.0 | |

Heat in carbon burned = 14,544 × 13,139 = 191,093,616 B.t.u.

H. Heat in Gas Made.

From the "elementary distribution," or burden sheet, there is made 91,283 pounds of gas, containing 13,957 pounds of carbon in it. Analysis of gas made averaged 13.06 $CO_2$ and 25.70 CO, and keeping this ratio intact, namely 55% CO, to 45% $CO_2$ by volume, we get the following:

| | FROM BURDEN SHEET | | | AVERAGE FROM TESTS | |
|---|---|---|---|---|---|
| Gas | Pounds | % Weight | % Volume | % Volume | % Weight |

## Blowing

The following facts were observed in connection with the Blowing Engines, Boilers, and other auxiliaries in connection with the Blast Furnace Plant:

A. Gas Blower required 8775# of gas to blow the air required per charge period.

A. Gas Electric Set required 15# of gas per KWH.

It required 1.7# of Dirty Gas to evaporate 1# of steam at 140#.

It required 1.6# of Clean Gas to evaporate 1# of steam at 140#.

Steam Blowing Engines consumed 25,000# of steam per charge period to blow the air required as found from water rate figured from indicator cards.

Available Gas. Conditon A.

| Dirty Gas | Pounds Dry Gas | B.t.u. |
|---|---|---|
| Out of furnace top | 91,283 | 122,930,642 |
| Leakage and bleeding, 10% | 9,128 | 12,293,064 |
| To stoves, dirty gas | 26,500 | 32,985,537 |
| Remaining to boilers | 55,655 | 77,652,041 |
| Steam generated, pounds | 32,740 | 39,091,560 |
| Blowing engines ......Steam u ed | 25,000 | 29,850,000 |

It was stated that the furnace tested was one rated at 600 tons of pig iron per day. During the week in which these simultaneous observations were taken 445 tons of pig iron were made per day, this being basic pig iron, and which is a fair figure for such practice. It was not desirable to make any unnecessary assumptions in the conditions, and accordingly the facts were taken as they were observed.

It may also be observed that the coke figure is high, and there are some furnaces with a better record and many with a worse record of coke consumption than this, but inasmuch as a furnace superintendent is greatly elated when a low figure for coke is obtained and is otherwise when it is the reverse, this figure is taken as representative.

The tabulated figures are given together with the calculations involved in each step, treating hot blast, the heat generated and absorbed, and the gas made separately.

In considering the use of the gas for power purposes in the operation of the furnace three conditions were available and on which data was obtainable.

Condition A was one in which the furnace was blown by steam-driven units, and this steam generated in boilers burning uncleaned or dirty gas. The efficiency of this system is obvious, and not economical, and accordingly a very little surplus steam for sale or use in the steel plant was available. It seems that exhaust steam turbines would be a profitable addition to such an equipment.

In condition B, and in which the blowing engines and auxiliaries were steam driven, the steam being generated in boiler burning cleaned gas, cleaned gas also was used in the stoves. The efficiency is much better. Although this system is conductive to better operation, and gives an appreciable amount of surplus steam for sale, still from a financial standpoint, considering the investment necessary for a cleaning equipment, and the fact that labor saved on the stoves and boilers would have to be used in the cleaning plant, it is doubtful if it would reduce cost of operation. However, economy could be obtained by using exhaust steam turbines.

In condition C, the use of gas engines shows the outcome of this advanced step towards economical use of the gas from a blast furnace. Some of the auxiliaries still use steam, but since there were six furnaces in the plant where this furnace was tested and all three conditions were present it was possible to figure the amount of steam used for pumps, etc., easily. This condition also represents the exact conditions on the furnace tested, namely, blown by gas engines, water pumped by steam pumps, and hoists operated electrically, as were the auxiliaries in the cleaning plant. Deducting the gas used in the stoves, in the gas engine blowers, and for use in the auxiliaries, there was remaining some 44,480 lb. of gas, which yielded 2965 kw-hours in electrical units, through a gas engine generating set, and at an efficiency of 18.7 per cent. Further economy could still further be obtained if use were made of the heat in the exhaust of the gas engines, and much steam generated which could be used in low-pressure turbines.

The three conditions tabulated make it a simple matter to figure the use of exhaust steam turbines applied to further economy. This question has been and still is very much discussed. It would be interesting to see just wherein the economy would balance best, in

## Conclusion

connection with steam blowing engines or with gas blowing engines and generator sets.

In the conclusion it may be noted that the stove efficiency on clean gas is 57.8 per cent and on dirty gas 45.9 per cent. The stoves themselves are open to much discussion, and the relative economy of two or three-pass stoves is an open question. The ratio of checker work is absurd when comparisons are made, and the relative value of side or central combustion chamber type of stoves has not been settled.

It seems that there is a very fertile field for effecting important improvement, and the figuring of heat balances under representative conditions should settle these points:

In all applications of new apparatus or remodeling of old, it is necessary to consider investment with the economy effected.

The regular operation obtained by using the dry blast is an example of a large investment required to effect large savings.

---

# Notes on Tube-Milling in All-Slime Cyanide Practice

BY W. J. PENTLAND

There seems to have been a general agreement among writers on the subject of tube-milling for cyanidation that the most desirable moisture content of the pulp is 38 (and sixteen decimals) per cent. It is true that many accounts have been published that seem to demonstrate this figure the ideal one. It is true also, we believe, that almost all of the tube-mills used in the experiments on correct moisture content were of the trunnion, small-discharge-opening type. Many of the early ideas on tube-milling no longer hold good. For example, it used to be said that "the finer the feed going to the tube-mill, the greater amount of net fine grinding done," and "the longer the pulp can be kept in the mill, the finer it will be ground." Many such comments were considered sound once, but are no longer heard. We believe it not improbable, therefore, that the old standard of 38 (and so many decimals) per cent moisture may go the way of some other assumptions. We now find many operators specifying 35 per cent moisture as preferable; to-morrow they will be saying 33 per cent, and may some time hold to 30 per cent.

Individual experiments are helpful, but they are not conclusive. Experimental conditions are rarely realized in practice. We endeavor to have practical conditions in our experiments, but rarely get them. Then we are apt to persuade ourselves that in subsequent practice we have the conditions of the experiments. Further, design of machinery and methods of operation change from time to time, and the standards of one period become untenable as practice in an art progresses. Thus, all early tube-mills were of the trunnion type; then came the tire type, with large discharge opening; and now we witness the Chalmers & Williams idea of inserting lifters behind perforated liner plates at the discharge end of the tube, virtually giving a discharge area of the whole diameter of the tube-mill.

In determining proper tube-milling conditions, it is one thing to have a single tube in a plant and be able to vary the system with facility, and quite another to have ten, twelve or fourteen tubes without equal facility in varying conditions. In the latter case it is usually necessary to decide upon a system and then carry it out over a period of a month or more and judge the average results. We believe that this method is likely to give more reliable information, as the experiment is subject to true working conditions.

It is usually true that a pulp must contain 38 per cent moisture in order to "get it through" the tube, or to "make the tube handle it," but not necessarily grind it to the required degree of fineness. Under such conditions we discharge the pulp to a classifier so that the unground portion may be returned to the tube-mill, and this is done because more work is demanded of the tube-mill than it can do under the conditions prescribed. In this respect the tube-mill is to be compared to a launder transporting pulp. If it is set practically level, as in the small-discharge-opening type, the more ore it has to handle, the more moisture must be supplied to transport the ore. The greater the inclination, or difference in fall between feed and discharge, the more ore can be passed as a thick pulp, or, in other words, the percentage of moisture required to carry it can be reduced.

### Duty of the Tube-Mill

It is a perfectly legitimate subject for debate whether the load going to the tube-mill should be in excess of the tube's capacity for grinding to the requisite degree of fineness, necessitating the return of a part of the pulp for regrinding, or be so adjusted that all of the required grinding is done in one passage of the pulp through the tube. If we are depending on the tube-mill to act as part of the agitation system, we may be compelled to return part of the pulp, but there are more economical agitators than tube-mills. If we can obtain proper grinding with one passage of the pulp through the tube, and also secure some agitation and dissolution of metal at the same time, we can well afford to build the subsequent agitators a little larger to secure dissolution of the metal that would have taken place in the tube-mill if we had returned part of the pulp to it.

The use of a closed circuit in tube-milling has become general practice, and this feature is closely related to the custom of grinding in 38 per cent moisture, for under no conditions will pulp of that moisture content pass through a tube-mill and be properly ground for all-sliming. At the same time we believe that there is no fixed and unalterable reason for returning part of the pulp to the tube-mill. It is the custom; just as it is custom, also, to use 38 per cent moisture. The advocates of this practice claim that if thicker pulp be fed to a tube-mill the machine will become "constipated" and will be unable to handle sufficient tonnage, and so for mechanical reasons it is necessary that the pulp be more dilute. As a matter of fact, this claim tells us exactly what is the matter with tube-mills of small discharge openings. It is admitted that such mills will not grind a sufficient tonnage of low-moisture pulp, and so we dilute it and circulate it through and through the mill until it is sufficiently ground.

### An Experiment with Graded Pulps

A simple experiment can be performed that will give some light on what takes place in a tube-mill. Take battery sand practically free from slime as it comes from the discharge of a classifier, and screen it into a number of sizes at intervals of 10 points between 10-mesh and 150-mesh. With each size make a pulp containing 38 per cent moisture, and by agitation of some kind keep the solids in suspension so that the pulp shall be of uniform consistency throughout. Then, commencing with the coarsest grade, take a sample of each pulp on a spatula. A certain quantity of the coarsest grade can be raised and retained on the spatula. Of the succeeding sizes less and less can be raised until, in the case of the 150-mesh pulp, scarcely any can be secured because the accompanying moisture affords sufficient carrying medium to keep the solids in suspension. Or, if each of the pulps were to be dumped on a flat surface, we would find that almost all of the coarsest grade would remain on the plate. There would be successively smaller quantities of the finer grades, and as we approached 150-mesh we would find more and more of the ore carried away in suspension, even with 38 per cent moisture.

We believe that this experiment indicates what occurs in a tube-mill. With the same percentage of moisture, finer sizes of sand are kept in suspension among the pebbles; and even though the whole mass of pebbles and pulp be rolling and grinding, the finer sands are still in suspension and sluicing around in the voids. The coarser sands are picked up by the pebbles and remain on their surfaces because the accompanying moisture is not sufficient to keep them in suspension. They are then in favorable position to be caught between pebbles and receive the requisite amount of grinding. We think that the pulp should be thick enough to permit the sand particles to cling to the pebbles as they rise with the mill. When the pulp is so thin that no particles cling to the pebbles, poor work is being done, and only the coarse sand is being satisfactorily ground.

It is readily seen that such thick pulp will not flow through a tube-mill that has feed and discharge openings at practically the same level; but it will flow when the discharge is lower than the feed, according to the difference in levels. Tube-mills of small discharge opening were responsible for the standard of 38 per cent moisture; and, in turn, adherence to that standard is responsible for the present tendency toward shortening tube-mills, from 20 feet and more, to 16 feet. With 38 per cent. moisture it is only of the coarser sands that the due proportion is ground, and that grinding takes place near the feed end of the mill. Then the remaining length of a long tube gives little service as a grinder and acts mainly as an agitator; therefore we shorten the tube, classify the ground pulp and return the oversize in the hope that it also will be duly ground in its next passage through the mill.

Diameter is an important factor in tube-mill design, but it is not "the whole thing," and increased diameter has the disadvantage of requiring more power for starting the mill. There is a tendency at present to regard sixteen feet as the most desirable length, on the assumption that practically no grinding is done beyond this point, making additional length useless. Some operators are inclined to believe that this is a mistaken idea, and that with thick pulps, or low moisture content, and a low discharge level, longer mills can be made to do satisfactory work. There is an advantage in using large units, but there is a limit to the practicable diameter, and greater capacity can then be had only by increasing the length.

### Cones Versus Drag Classifiers

At one time is was customary to use cones for thickening tube-mill feed; but these devices gave trouble from the beginning, and only by unremitting care and attention could they be made to furnish pulp even as thick as 38 per cent moisture. We believe, however, that as drag classifiers displace cones, and operators have thicker pulps to experiment with, they will regard them as more desirable. As tire-type mills come into greater use, the advantage of quicker discharge will be observed; and those who have condemned the long tube-mills will try discharging with the lifter device over the whole diameter of the tube, and will find that the long mills will grind a larger tonnage than the shorter ones.

Fresh battery sand is easier to grind to slime than is returned sand that passed through the tube-mill and classifier. The former is sharp and angular; the latter is rounded. The former can be more readily dewatered than the latter, and will be more readily picked up by the pebbles in the mill. This can be demonstrated practically by comparing the work of tube-mills on sand from old tailing dumps and fresh battery sand from the same ore.

### Effect of Size of Feed on Capacity

It has been observed that some operators deceive themselves as to the net work their tube-mills are doing. If they are treating 100 tons of ore per day, and the pulp going to the treatment vats contains 80 per cent minus 200-mesh, they assume that the tube-mills are grinding 80 tons per day, forgetting that with 16-mesh screens on the battery some 38 to 40 tons was already ground to 200-mesh before passing to the tubes, so that the latter are really grinding but 40 to 42 tons to the required mesh. In this connection we recall a neighboring operator who had 14 tube-mills under his direction, and had always estimated their work at 40 odd tons daily. On properly revising his estimates he found the figure reduced to about 28 tons daily. Feeling that the tube-mills were not doing as much as they should, he endeavored to improve the service. By loading the mills with additional pebbles, feeding the thickest pulp his launders would carry, and substituting 6-mesh screens on the batteries for 16-mesh, he brought the tonnage up from 650 to 1000 tons daily and still had 80 per cent minus 200-mesh solids in his final pulp. This mill follows the practice of open circuit; the pulp does not return to classifiers after passing through the tubes, but flows through a revolving trommel that removes any coarse sand that may accidentally occur in the pulp. The trommel has a 16-mesh screen.

A personal experience may be cited. We had 200 stamps, cone classifiers and thickeners, two tube-mills 5 ft. by 30 ft. and seven tube-mills 4 ft. by 22 ft. The ground pulp was again classified in cones. Following the dictum that the finer the sand going to the tubes the better the product, we used 35 and 40-mesh screens on the batteries, yielding a product containing about 60 per cent minus 200-mesh solids. From 730 to 750 tons could be treated, giving a final pulp of 80 per cent minus 200-mesh. By substituting 25-mesh screens on 100 stamps and 30 or 35-mesh on the other hundred, we were enabled to raise the tonnage to from 830 to 850 tons, but this was the most we could get through the tube-mills. With cone thickeners we had to give constant attention to keep the moisture down to 38 per cent.

We then hung up 100 stamps, put 8 and 10-mesh screens on the remaining hundred, rearranged and improved the cone system of classification and thickening, and added three tube-mills 5 ft. by 24 ft. This system enabled us to increase capacity to 1050 tons daily; while battery, crusher and conveyor costs that used to total 35 cents went down to 17 cents.

Some of the tube-mills received battery pulp only; others received a mixture of battery pulp and oversize returned from classifiers; and still others received only return feed. The last was itself classified or graded by the arrangement of the distributing box at the top of the elevator, so that some mills received fine returned sand and others coarse. We had continuous opportunity to observe the difference in grinding various sizes of sand. Coarse sand dewaters easily and grinds better in the tube-mill; fine sand is difficult to dewater in cones, and is harder to grind. With coarse feeds we could get lower moisture, greater tonnage and better ground pulp; with the finer feeds it was almost impossible to get low moisture, the tonnage was reduced, and the product never contained as much minus 200-mesh solids as was secured from the coarser feeds.

### Grinding Oxidized and Sulphide Ores

Our mill ore consisted of 950 tons of yellow, oxidized ore, assaying about $7 per ton, and 100 tons of blue, sulphide ore, assaying about $30 per ton. There was never much difference between the mine and mill superintendents regarding the tonnage or value of the yellow ore; but there was a continual difference between them as to the blue ore, as this factor entered strongly into the calculations at the end of the month. So we can safely assume that the figures for tonnage of blue ore, as agreed upon by the superintendents and given herewith, are correct.

Formerly the two classes of ore were mixed in the main bin, but on account of the more refractory character of the blue ore it was decided to give each separate treatment.[1] Ten stamps were set aside for blue ore, and a special bin provided. Separate classifying and thickening cones also were added. Later a drag classifier was substituted for the cones. The tube-mill was 4 ft. by 22 ft. and had a discharge opening about 18 inches in diameter, being of the tire type.

Extensive experiments were conducted on kind and size of pebble load, and on moisture content of pulp, each experiment being under way for a number of days with the regular attendants on shift. Battery screens were 7, 8, 10 or 12-mesh and were varied to give the desired tonnages under different conditions.

With iron pebbles or grinders, cast-iron ovals or old bolts cut into five-inch lengths, it was possible to grind 120 tons of blue ore daily and get a final pulp containing from 86 to 88 per cent minus 200-mesh. The moisture was carried as low as 25 per cent, though at this consistency the pulp was really too thick to work through the mill, and only about 100 tons could be handled. At 28 to 29 per cent moisture, however, 120 tons could be treated—that is, a total of 120 tons through stamps and tube-mill. From 30 to 35 per cent minus 200-mesh solids was produced in the batteries, leaving only about 70 tons actually ground to minus 200-mesh in the tube-mill. The power requirement under these conditions was about 95 hp., and as only a 75-hp. motor was available, a run of a few days only was possible.

With a mixture of iron grinders and imported pebbles, or using mine rock for pebbles, the horse-power was reduced to 80 or 85, and the total tonnage treated to 100, still obtaining a final pulp with over 85 per cent minus 200-mesh solids.

The final conclusion was to treat 80 to 85 tons of blue ore daily, using mainly mine rock for grinders, with a small daily addition of imported pebbles. The moisture was maintained at 31 to 32 per cent.

### Summary and Comparison of Results

While using 200 stamps with 25 and 35-mesh screens on the batteries, from 50 to 55 per cent of the battery pulp was minus 200-mesh, and the final tube-mill pulp contained 80 per cent minus 200-mesh. Under these conditions each of nine tube-mills ground on an average 25 tons to minus 200-mesh. Since using only 100 stamps, with 8 to 10-mesh screen on the batteries, giving a battery pulp containing only 30 to 33 per cent minus 200-mesh, each of twelve tube-mills averages 42 tons net. Drag classifiers have now been installed throughout the mill and the cones are on the scrap heap, as also is 38 (and so many decimals) per cent moisture for tube-mill feed.

Of these tube-mills, four were trunnion type with small discharge openings; eight were tire type with about 18-in. discharge openings. There were two pairs of 4 ft. by 22 ft. tubes, each pair comprising one trunnion type and one tire type. There was one pair of trunnion type only. The remaining mills, two 5 ft. by 30 ft., and one 4 ft. by 22 ft., all were of tire type with 18-in. discharge openings. With the first two pairs mentioned, it was quite convenient to compare the work of each type, and it was observed that the trunnion type never gave as good results in either quantity or quality as did the tire type.

### Effect of Speed in Grinding

Grinding in tube-mills is done by the pebbles sliding or rubbing over or against one another, and not by falling against each other. Very little grinding is done between pebbles and the tube-mill liner. The revolution of the mill should be so regulated that centrifugal force will raise the load high enough to permit the pebbles to slide over each other, but it should never be sufficient to permit the pebbles to fall through clear space. The proper mean speed probably results in letting some of the upper pebbles fall clear while the main body slides. This result can be obtained better through centrifugal force than by liners adapted to carry the whole load up.

---

[1] The blue pulp was agitated separately and then combined with the yellow, receiving also the agitation considered necessary for the latter. This method of treatment is an example of the practice which I suggested in a former article in this Journal, October, 1911, page 6[illegible]1, wherein I proposed giving the most refractory part of an ore its due treatment apart from the rest, instead of subjecting the whole ore to the treatment necessary for only a small portion of it.

Irregular-shaped mine rock used for grinding probably does little work until it has been ground to round or oval shape, and tube-mill power for this purpose is expensive. The same amount of power expended on grinding with round pebbles would accomplish much useful work. Feeding pebbles through the scoop is slow work, and pebbles that miss the scoop and fall in the feed-box may cause the breaking of the scoop. On removing the door of a tube-mill we usually find the pebbles evenly arranged throughout the mill, according to size, regardless of the method of feeding them.

When a tube-mill is grinding its full load a distinct rise in temperature of the shell can be noted. If the pebble load is light, or the moisture content of the pulp so high that the increased temperature is not apparent, the mill is not doing the work it can be made to do.

### Relining a Tube-Mill

With El Oro liners a tube-mill can be relined in 14 to 16 hours. The new liners should be piled near the tube on the previous day. At 5 a. m. stop the mill, take off the man-hole plates and start the mill again, allowing the pebbles to discharge on the floor, then stop the mill again, loosen the bolts holding the liners, taking the nuts off and driving the bolts to the inside, where they are gathered up. Now start the mill again, and inside of half an hour the plates will have fallen and almost all of them will be lying on the floor beneath the mill. The new plates and pebbles can be replaced, and the mill be in operation again by 8 p. m.

Denver, Colo.

## Copper in Babbitt Metal

BY E. W. HAGMAIER

Babbitt metals contain copper in varying amounts from several per cent to a trace. While copper is not the most difficult metal to determine in the alloy, still the steps necessary to obtain the copper in suitable form are somewhat tedious.

The writer has met with very good success by using the following scheme.

Place 1 gram of the filings or sawings in a 250-c.c. beaker, add 15 c.c. of hot water, and sufficient tartaric acid to hold all the tin and antimony in solution, run in 5 c.c. of nitric acid from a pipette and boil until the alloy is all dissolved. If the solution is milky in appearance, there has not been sufficient tartaric acid added, and the determination must be started over, with more tartaric acid. When solution is complete remove the beaker from the plate, cool, and add 5 c.c. of sulphuric acid, place on the plate and boil until all the nitric acid is driven off. This can be determined when no more brown fumes are expelled. This will require about five minutes boiling. As soon as the nitric acid is driven off remove from the plate or the tartaric acid will char. Cool, add 50 c.c. of water, allow the lead sulphate to settle and filter, washing with 2 per cent sulphuric acid solution. Several washings can be made by decantation before transferring the bulk of the precipitate to the paper. This precipitate can be used to determine the lead by dissolving off the paper with ammonium acetate and acetic acid and precipitating the lead as chromate. The filtrate from the lead sulphate is made up to 400-500 c.c., 1 or 2 c.c. of hydrochloric acid added, a strip of copper free aluminium added, and the beaker placed on the back of the plate, and the copper will be thrown out. With careful manipulation all of the copper can be thrown out in this way after which it can be filtered off and determined electrolytically or by titration.

Babcock-Hagmaier Laboratories,
Lackawanna, N. Y.

## Report of the Chemical and Dyestuff Committee of the New York Section of the American Chemical Society

At the meeting of the New York section of the American Chemical Society on Nov. 6 the Chemical and Dyestuff Committee, appointed at the preceding meeting, made its formal report.

The report was presented by the committee's chairman, Dr. BERNHARD C. HESSE, the other members of the committee being Messrs. J. B. F. HERRESHOFF, H. A. METZ, I. F. STONE, D. W. JAYNE, J. MERRITT MATTHEWS and ALLEN ROGERS.

On motion of Mr. Thomas J. Parker, the report was unanimously adopted. In the discussion Dr. L. H. Baekeland pointed out that time is needed to bring about an extension of the American chemical industries and that the success of an American coal-tar industry required the creation of a home market for its by-products.

In view of the authoritative character of the report we herewith give it in full:

### Committee's Report

*To the New York Section, American Chemical Society:*

At the meeting on Oct. 9, 1914, the chairman of this section was authorized to appoint a committee to investigate into the feasibility of expanding the chemical and dyestuff industry in the United States and to report to this section on Nov. 6, 1914.

The undersigned committee was appointed Oct. 15 and at once proceeded. It addressed letters of invitation to co-operate to those who have been most active in the public prints in urging expanding of the chemical, and particularly the dyestuff, industry in the United States; further, an invitation was extended to the maker of the motion, which resulted in the appointment of this committee. The assistance from these is nil.

A request was addressed to trade publications in the city of New York and to some of the metropolitan dailies; in all nine such publications were requested to publish a suggested notice for the purpose of inviting co-operation; the object of this committee was set forth and request was made that suggestions be mailed to the chairman of this committee. All but one of these publications have complied with that request. No help has been obtained by this committee from any suggestions mailed to it as a result of this publicity.

Your committee has carefully considered all the public suggestions as to methods of improvement and has searched through the governmental regulations of the belligerent nations as to embargo and as to contraband of war, in order to construct therefrom a list of chemicals, inclusive of dyestuffs, which have thereby been shut off from the United States, in the hope of thus being placed in a position to make specific recommendations of value.

### General Conditions of American Chemical Industries

It can be fairly stated that, in general, the chemical industry of this country is efficiently exploited and is making full use of all the opportunities presented to it under the normal conditions existing prior to the state of hostilities. Some of the chemicals which are imported from abroad are made in considerable amounts in this country as well, and the amount imported under normal conditions depends upon the ordinary normal fluctuations of business conditions both here and abroad. With the stoppage of this foreign supply the domestic production was not at once capable of making up the deficiency, but in a number of instances the American manufacturers have taken steps to increase their capacity, and the strain in the market of those particular things will exist no longer than it will require to extend the manufacturing facilities to the proper extent.

Among these are ammonia salts, barium chloride, barium nitrate, bleaching powder, sodium cyanide, yellow prussiate, sodium nitrite, sodium hydrosulfite, zinc dust.

If, however, it be desired and if public necessity requires the introduction of the manufacture of explosives and further chemicals and dyestuffs into our home industry, such as *coal-tar product explosives, pharmaceuticals, medicinals and other intermediates and finished coal-tar dyes*, then alterations of our tariff law are inevitable, and the consumers in the first place and the public in general must share in the burden thus imposed. If conditions of national defense in case of attack by a foreign power require us to manufacture our own explosives, and to be in that regard independent of all foreign nations at all times, or if our textile industries or any other of our industries requiring coal-tar chemicals, such as dyestuffs, shall forever be protected and made independent of foreign nations for the supply of those materials, then the nation as a whole must bear the burden incident to such expansion. Under existing circumstances private enterprise and private capital have gone their limit. They have reached the limit for two reasons:

I. The explosive, dye and similar industries abroad, just referred to, are in a state of high development and of refined organization, and are financially the best suited to carry on an offensive campaign against any nation attempting to take business away from them.

II. Domestic manufacturers are prohibited by law from making use of co-operative commercial devices, such as pools, trusts, manufacturing and selling agreements and the like, whereas such devices are wholly lawful abroad, and are encouraged by the respective governments. In other words, the American chemical industry is expected to cope with the foreign industry while both its own arms are tied behind its back and its opponents have full and free use of their arms.

### An Anti-Dumping Clause Required

The remedies required would be an effective anti-dumping clause that would certainly prevent underselling of domestic manufacturers in the United States by unfair methods. What the form of such clause shall be is a problem with which your committee is unable to cope; it is strictly a law-making and law-enforcing problem, and is allied to the usual problem of determining undervaluation as heretofore carried on by our Treasury Department; it, however, is a much more refined problem than the older problem of proving undervaluation. Nevertheless, your committee believes that with such a mechanism in our law that much would be done toward encouraging our chemical industries.

### Change in Tariff Law Required

According to the best information that your committee can gather, such an anti-dumping clause alone would not be sufficient, however, to create complete and independent domestic coal-tar explosives, dyestuffs and medicinals industries. It has been conclusively demonstrated during the past thirty years that the present tariff rate of 30 per cent on dyestuffs is not sufficient to induce the domestic dyestuff industry to expand at a rate comparable with the consumption of dyestuffs in this country, and that therefore all dyestuffs made from coal tar, whether they be aniline dyes or alizarin, or alizarin dyes, or anthracene dyes or indigo, so long as they are made in whole or in part from products of or obtainable from coal tar, should all be assessed alike, namely, 30 per cent ad valorem plus 7½ cents per pound specific, and that all manufactured products of or obtainable from coal tar, themselves not dyes or colors and not medicinal, shall be taxed 15 per cent ad valorem and 3¾ cents per pound specific.

The best information and judgment your committee can obtain is that the above manufactured products of coal tar, not dyes and not colors and not medicinal, should carry one-half the duty of the finished coal-tar dye and that the above rate of 30 per cent ad valorem and 7½ cents specific would probably be sufficient to encourage and enable domestic manufacturers to expand their operations to such an extent as to supply a very material increase in, if not the whole, of these commodities consumed in this country.

The reason for a specific duty is to protect the domestic manufacturer in the manufacture of the relatively cheap dyes, such as the cheap scarlets, the cheap yellows and the like, whose prices abroad are in the neighborhood of from 12 cents to 20 cents per pound, with dyes of that type 30 per cent ad valorem would not offer so serious an obstacle to importation and underselling thereof as does the 7½ cents per pound specific; on the other hand, on dyes whose prices are $1 and upward per pound the function of the 7½ cents specific more nearly approaches zero. That is, with the cheap dyes the chief function lies in the specific portion of the duty, and with the expensive dyes the chief function lies with the ad valorem portion of the duty.

This is said to be the price the nation will have to pay to have a complete self-contained and independent coal-tar chemical industry. However, it must be remembered that if such an industry be created and importation of coal-tar products, inclusive of intermediates and dyes, is restricted, its ultimate effect upon the Federal revenues will have to be considered. It will, therefore, be necessary to determine carefully if the advantages to be gained are equal to the price to be paid.

### No Compulsory Working Clause Required

This committee is a unit in the belief that an alteration of our patent laws aiming at compulsory working or compulsory licensing would not be any substantial benefit to this industry or to the country as a whole. Twenty-nine countries have attempted compulsory licensing clauses and fifty-six countries have attempted compulsory working clauses, and the best information your committee can obtain is that in none of these attempts has there been any appreciable measure of success. While it may be true that under extraordinary conditions, such as now exist, compulsory licensing might have some advantage, yet it is equally true that in normal times the disadvantage due to compulsory licensing or compulsory working would more than overbalance any advantage at all likely to be obtained under stress of unusual conditions.

In none of the countries where there have been working or licensing clauses, or both, co-extensive with the existence of the coal-tar chemical industry has there been established any real coal-tar chemical industry and your committee does not feel that an alteration in our present patent laws could be made which would be effective against foreigners and at the same time not be onerous and a hardship to domestic inventors. Your committee believes that in the long run and in the final outcome, our present system with regard to working and licensing is as efficient as that of any other country. In the dyestuff industry in particular there are so many non-patented commercial products and so many commercial products once patented now free from patent restraint that their production alone would from a basis for a very considerable industry, and your committee feels that the way to encourage that industry, if the establishment of that industry in this country be a national necessity, is through a change in the tariff and the additional anti-dumping feature in the administration of the tariff and not through any change in the patent laws.

Once established, such an industry could develop and ultimately cope with any foreign combination upon fair and equal terms. Over 90 per cent of the tonnage and of the individual dyes used in the United States will be free from any patent restraint within the next four years; over 75 per cent of the dyes are now in that condition.

### Availability of Raw Materials for Coal Tar Industry

The best information your committee has so far been able to gather is that this country can produce so-called coal-tar raw material in amounts sufficient for the needs of a complete domestic coal-tar chemical industry, inclusive of explosives and dyes, provided there is a certainty of outlet as to volume and continuity. Those engaged in manufacture here do not want to expand unless the dye users are willing to make corresponding contracts. In other words, it is a closed circle. If the dye users will contract sufficiently with the dye makers, the dye makers will contract with the coal-tar distillers and the industry will take a start. The initiative rests wholly with the users; if they cannot afford to contract the dye makers and the distillers cannot afford to make their contracts and additional investments.

### Coal Tar Products

*Benzol, toluol* and the like are produced in sufficient amount in present installations of by-product coke ovens to provide all of these things that would be needed for a coal-tar chemical industry of a magnitude sufficient to supply the United States market; the separation of these materials from the gas that carries them is dependent upon the market and the demand therefor. There is no inherent defect in our coke industry with regard to the actual making of these things; the only question involved is whether it be more profitable to burn the benzol, toluol and the like contained in the gas as a fuel than to separate them from each other for purposes of sale. Ample supply can be provided before any plant that could use benzol and the like for dyestuff making could be erected in the United States and thereafter the supply of these materials can readily be kept up to any requirements.

The materials of the preceding paragraph are the ones used in the coal-tar explosives industry, as well as in the coal-tar medicinals and dyestuffs industries. Each of these three industries co-operates with the others to make full use of those materials, alone none can fully make use thereof nor succeed; the correct and proper utilization of these materials requires successful co-existence of all three industries in one and the same country.

*Naphthalene* and *anthracene* are contained in the tars produced in the United States in an amount sufficient for the needs of a domestic dystuff industry, and it is merely a question whether it is more profitable to leave them in the creosote oil, where they now occur, or to separate them out of such oil and refine them for purposes of dye manufacture. Ample supply of either of them could be produced and provided at the same time or shortly after any plant could be erected in the United States for the use of these things in the production of dyes.

What has been said with regard to the supplies of naphthalene is also true of the supplies of *cresole*.

All the *creosote oil* contained in the total amount of coke-oven tar now made is separated from it and used. Increased production of creosote oil requires a greater production of tar, and a greater production of tar is dependent upon increased installation of recovery coke ovens.

*Phenol* or *carbolic acid* supply is primarily dependent upon our deliberately selected method of coal treatment; to change that treatment so as to get more phenol would entail abandonment of other advantages which would not be compensated for by the increased amount of phenol so produced. Under present circumstances freights and haulages play an important part. At isolated plants, separated by considerable distances from each other, small amounts of phenol are produced, and the separation of the phenol at such individual places would be economically unprofitable, and in order to concentrate this amount of phenol to or at a point where separation could be conducted profitably would entail freight haulages much in excess of the value of the phenol that would thus be transported.

The only source of *phenol* in sight is that produced synthetically from benzol by means of sulfonation and subsequent melting with caustic soda; this depends in turn upon our benzol supply, and would be profitable only so long as the United States market is not killed by the dumping of foreign phenol thereon, whether such phenol be synthetic or distilled.

*Salicylic* production depends upon availability of phenol, and the production of benzoic acid depends upon the availability of toluol, which has heretofore been discussed.

*Phthalic acid* made from naphthalene by means of bichromate cannot successfully compete with the mercury and sulphuric acid process, which is protected by patents having about three years more to run.

### Miscellaneous Chemicals and Raw Materials

*Acetic anhydride* can be made without trouble in this country, and will be made in this country as soon as the domestic demand is large enough and steady enough to warrant the installation of a suitable plant.

*Nitric Acid.*—All countries with the exception of possibly Norway and the countries importing from Norway are dependent upon Chile for the raw material for making nitric acid. It will not be profitable to make nitric acid from air in the United States until the value of the electric horse-power reaches a level of $3 or $4 a year, as it is in Norway.

*Ammonia* and its salts all depend upon recovery coke ovens, and such recovery plants are increasing as fast as circumstances will permit.

*Barium chloride* and other compounds of barium may be made from domestic barytes. A number of attemps have hitherto been made, but with indifferent success. Factories established within the last year promise to be successful.

*Magnesium chloride* of a sufficient purity to be used in the production of flooring is almost generally made from magnesite found in Greece, which is the only deposit known having sufficiently high purity; there are reports of suitable deposits in California and in Lower California, and with the completion of the Panama Canal the question of freights, which seems hitherto to have stood in the way of developing these deposits, may be eliminated. Other sources, less remote from centers of consumption, and using other materials, e.g., brine waste are about to be successfully operated.

*Manganese* in the form of pyrolusite is not known to occur in paying deposits in the United States; these are practically all in the Caucasus.

*Potash.*—In view of the great exertions that have been made for a number of years, both on the part of the Federal government through a number of its departments and a great many different groups of capitalists, there is nothing to be said in this report that would be of any value with regard to increased production of potash either as fertilizer or as a chemical.

*Yellow prussiate* and *sodium cyanide* can be and have been made from domestic materials in such an amount as to provide practically the entire consumption or a great portion thereof in this country so long as there was a sufficient duty on them; the present duty is not enough to protect the American manufacturer, and those who were engaged therein have in large measure withdrawn from the business, but some are reported to be taking up manufacture cautiously and in limited amount.

*Hydrosulphites* in solution can be made from domestic materials without interference with any patent rights; the production of solid salts and derivatives are, however, still protected by patents that have a few years more to run.

*Sodium nitrite* is produced more cheaply as a byproduct in Norway than it can be produced anywhere in the world; unless the price of the electric horsepower in this country sinks to a $3 or $4 level per year, as in Norway, this product cannot be manufactured in the United States.

*Oxalic acid* is and has been made to some extent in this country, and the information coming to your committee is that suitable efforts are being made to expand the capacity of existing plants.

*Tartaric Acid and Citric Acid.*—To make this country independent of others with respect to tartaic acid and citric acid would call for radical changes on the part of our grape growers and our lemon growers as to the policy of their business.

It is probably true that edible grapes do not produce argols (the crude material for tartaric acid) very largely, and that our domestic lemons do not produce as large yields of juice (the crude material for citric acid) nor as high an acidity as do the Italian lemons; therefore, an independent supply of the raw materials produced in the United States for tartaric and citric acids is, in the first instance, an agricultural problem, and, in the second instance, a market problem.

Finally, it should be pointed out that the United States is by no means the only country whose chemical and allied business has been strained or upset by the European war. Each and every other country has felt the strain. British committees have gone into the same subject of expanding British chemical industries, and not only that, but also into the question of making their very basic necessities, and the reports have so far been adverse to any immediate relief by domestic manufacture. The Boston Chamber of Commerce, through its committees, has arrived at the same conclusions for this country.

It is further clear that the stability of a complete domestic chemical industry, insofar as it depends upon foreign supplies, is bound up to a successful merchant marine and to an efficient foreign banking condition just as in all our foreign business.

### Findings and Conclusions

Your committee finds as follows, as to the facts:

I. Prior to the hostilities the domestic chemical industry was utilizing and exploiting every reasonable opportunity to its full extent.

II. Since the outbreak of hostilities domestic industry has increased its output just as fast as physical means could be provided and physical obstacles overcome.

III. Since the outbreak of hostilities domestic plants that had theretofore been shut down or partly dismantled because of disastrous foreign competition are said to have resumed operation, with caution.

IV. That a 30 per cent duty on some coal-tar dyes for over thirty years has not produced a real coal-tar dye industry in this country.

Your committee submits its conclusions as follows:

A. To prevent the unfair underselling alleged to be practiced by foreigners in this country, the adoption of an effective anti-dumping clause.

B. The so-called coal-tar "intermediates" which are the basis of the coal-tar chemical industry, inclusive of explosives, medicinals, and dyestuffs, should be assessed one-half of whatever the finished dyes are taxed for tariff purposes; all coal-tar dyes without exception to be taxed alike, namely, 30 per cent ad valorem and $7\frac{1}{2}$ cents per pound specific.

C. Changes in the patent laws such as by compulsory licensing or compulsory working clauses are wholly ineffective, do more harm than good, and should not be attempted.

Your committee recommends that this report be submitted to the appropriate committees of Congress. Further, that this report be forwarded to interested organizations.

Respectfully submitted,
BERNARD C. HESSE, *Chairman.*
J. B. F. HERRESHOFF.
H. A. METZ.
I. F. STONE.
D. W. JAYNE.
J. MERRITT MATTHEWS.
ALLEN ROGERS.

## Philadelphia Meeting of American Institute of Chemical Engineers

The seventh annual meeting of the American Institute of Chemical Engineers will be held in Philadelphia from Dec. 2 to 5, 1914. Hotel headquarters will be at the Hotel Adelphia.

Business meetings will be held at the Hotel Adelphia on Wednesday, Dec. 2, 10:30 a. m. and at the Franklin Institute on Friday, Dec. 4, 9 a. m. Sessions for the reading and discussion of papers are scheduled as follows:

Dec. 2, 11:15 a. m. (Hotel Adelphia):

D. D. Jackson, The manufacture and application of the artificial zeolites (permutite) in water softening.

Allerton S. Cushman and George W. Coggeshall, Feldspar as a possible source of American potash.

Dec. 2, 8:15 p. m. (Franklin Institute):

George O. Smith, Distribution of Industrial Opportunities.

Dec. 4, 10 a. m. (Franklin Institute):

John V. N. Dorr, Hydrometallurgical apparatus and its use in chemical engineering.

E. H. French and James R. Withrow, Hardwood distillation.

Jokichi Takamine, The chemical industries of Japan.

Bernhard C. Hesse, Need of up-to-date manufacturing statistics.

Dec. 4, 8:15 p. m. (University of Pennsylvania):

S. P. Sadtler and S. S. Sadtler, Ore flotation.

Edw. Gudeman, Aspects of some chemical industries in the United States.

Excursions will be made on Wednesday afternoon to the Atlantic Refining Company and United Gas Improvement Company, on Thursday (all day) to the Welsbach Company works in Gloucester, N. J., the New York Shipbuilding Company, and the Farr & Bailey Linoleum Works in Camden, N. J., on Friday afternoon to the Commercial Museums and the Laboratories of the University of Pennsylvania, and on Saturady to the Barrett Manufacturing Company in Frankford, Philadelphia. A subscription dinner will be held on the evening of Thursday at the Hotel Adelphia.

# Chloridizing Ores at Silver City, Utah.

*(Editorial Correspondence)*

Interest in the revival of chloridizing processes in Utah has centered mainly in the work of N. C. Christensen, Jr., at Silver City, and Theodore P. Holt and George H. Dern, at Park City. Former issues of METALLURGICAL AND CHEMICAL ENGINEERING[1] have made frequent reference to these developments, and one issue[2] described the Park City process in detail. The principles underlying the work of Mr. Christensen at Silver City are similar to those applied at Park City, but the method of application is quite different as will appear from the following notes.

### The Knight-Christensen Metallurgical Co.

The mill at Silver City, Utah, shown in Fig. 1, was erected primarily for the local treatment of ore from the mines of Mr. Jesse Knight, who has been deeply interested in the development of a metallurgical process and has given commendable financial support to the ideas of Mr. Christensen. The ores from the Knight mines afforded an excellent variety of oxidized, sulphide and silicious material from which to make a mixture most suitable to the process of treatment. Silver is the metal of principal value; copper, gold and lead also occur, and are of importance in about the order named. In metal contents the different ores range from 4 to 30 oz. silver and 0.03 to 0.20 oz. gold per ton, 1 to 8 per cent lead, and from a trace of 1.75 per cent copper.

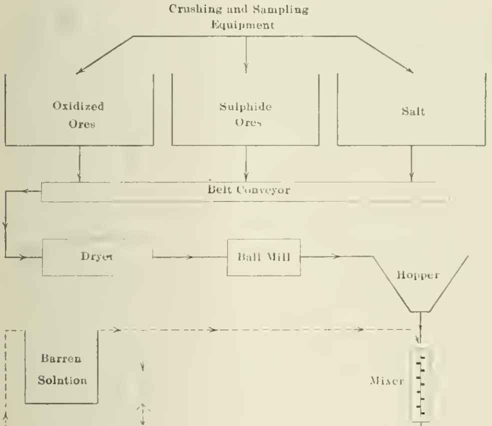

FIG. 1.—ORE-TREATMENT DIAGRAM, KNIGHT-CHRISTENSEN MILL

The sulphides provide the fuel necessary in the chloridizing roast, and in this respect the metallurgical conditions differ from those in the plant at Park City where coal is added to the ore-mixture before roasting. Otherwise the process is similar except in method of application. Briefly, it consists in roasting a mixture of ores and salt; condensing the acid roaster gases in salt solution; leaching the roasted ore with this solution, and precipitating the metals successively—gold and silver on copper, copper on lead, and electrolyzing the final lead solution. The diagram in Fig. 1 presents the main features of the process.

### Preparation of the Ore-Mixture

The crushing and sampling department comprises the usual machinery for such purposes and affords accurate samples of ore received from the different mines. Ores and salt are both crushed to $\frac{3}{8}$-in. before delivery to their respective storage bins. Adjustable mechanical feeders deliver fixed quantities of the different ores and salt onto a belt conveyor that feeds the dryer. An effort is made to maintain about 4 per cent of pyrite in the mixture, and salt is added to the extent of 8 to 10 per cent. Salt costs $4.15 per ton at the mill.

From the dryer the mixture is passed to the ball mill, shown in Fig. 2, where it is ground to the requisite degree of fineness. This ranges from 8 to 20-mesh and depends on the character of the ore under treatment. It is recognized that inasmuch as sulphides are used for fuel, the finer they are ground the more uniform their distribution through the mixture, with consequent reduction in quantity required and improvement of the chloridizing roast. Compact, silicious ores require finer grinding than do the more porous oxidized iron ores. Salt, of course, becomes thoroughly disseminated through the mass in the process of grinding.

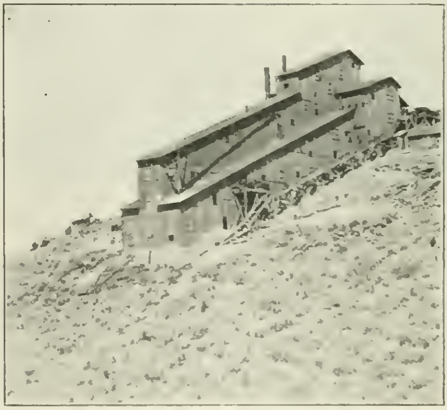

FIG. 2.—KNIGHT-CHRISTENSEN MILL, SILVER CITY, UTAH

The next step is the addition of 8 to 10 per cent of barren mill solution to the ore-mixture. It is essential that this moisture be uniformly distributed throughout the mass in order that the physical condition of the ore-bed on the furnace hearth shall be the same at all points. A simple and effective mixing device has been constructed, consisting of a vertical pipe 4 ft. long and 6 in. in diameter, within which is mounted a central revoluble shaft provided with horizontally projecting teeth arranged at intervals along its length. The shaft rests in a step-bearing and makes 480 r.p.m. Ore and solution are fed at the top of the pipe, and a uniformly moist, porous mixture is delivered at the bottom. Several mixing devices had been tried prior to the adoption of this one, but none gave satisfaction.

[2] Chlorination at Park City, Utah, this journal, July and August, 1914, pp. 431 and 492, respectively.

### Chloridizing-Roasting

The roasting furnace consists essentially of a horizontal, annular, revolving, perforated hearth, 22 ft. outside and 10 ft. inside diameter. A feed hopper is erected at one point over the hearth, and adjacent to it on either side is the ignition box and the discharging device. The hearth is constantly under downward suction from a fan placed at one side of the furnace. A roaster of this size operating under the conditions existing at Silver City has a capacity of 300 tons in 24 hours.

In operation, the hearth makes one revolution in 40 minutes. The ore is fed onto the hearth continuously in a loose, porous layer from 4 to 8 in. deep, according to the fineness of the mixture. Finely crushed ores are deposited in shallow beds. The grates have perforations ⅛ in. by 1 in. Ignition of the charge is started as it passes under the oil-fired furnace and is continued by the down draft throughout the revolution of the hearth to the point of discharge. Careful adjustment of the temperature is required to get uniform ignition and prevent sintering the ore, and the fire-box is kept at a dull red heat with an oxidizing atmosphere. The temperature of the roast is about 700 deg. C. It can run as low as 500 deg., but may not exceed 800 deg. without danger of loss by volatilization. Oil consumption varies with the depth of the bed and fineness of the ore, and ranges from ½ to 1 gallon per ton. The cost of oil, crude distillate, is about ten cents per gallon in tank-car lots.

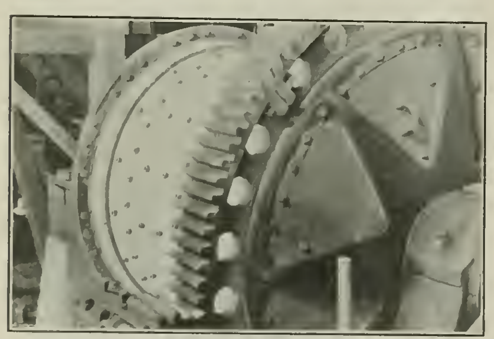

FIG. 3.—BALL MILL, KNIGHT-CHRISTENSEN MILL

The roast is loosened and detached from the hearth by a plow that extends nearly to the hearth surface. A screw conveyor engages the loose mass and removes it. A view of this mechanism is given in Fig. 3, which shows also a part of the annular hearth and the feed hopper. In order to provide a layer of coarse material on the hearth beneath the raw charge, to protect the grate from corrosion and prevent fine ore running through the perforations, a portion of the roasted ore is allowed to pass over the plow and fall onto the hearth just before passing under the feed hopper. The chloridized ore is still hot when removed from the roaster. It is elevated to a storage hopper where chloridization continues until such time as the ore is withdrawn and charged into the leaching barrels.

As the ore-bed is constantly under diminished pressure, no chlorine or other fumes contaminate the mill atmosphere. A steel fan driven by a 15-hp motor draws the fumes from beneath the hearth and forces them into wooden towers containing horizontal wooden partitions through which barren mill solution is descending. Emerging from the towers the solution contains $SO_2$, Cl, and about 2½ per cent HCl, and is almost at boilin gtemperature. This is the active leaching solution with which the chloridized ore is treated. Of course, the solution gradually becomes saturated with salt as it circulates through the leaching barrels.

### Metals Go Into Solution Rapidly

Ore and solution are both hot when they are brought together in the leaching barrels, and conditions are most favorable for rapid solution of the chloridized metals. The barrels are spherical in shape, mounted on trunnions, and contain filter-bottoms. A charge consists of five tons of ore, and solution in the ratio of 2½ to 1 of ore. When a barrel is full it is allowed to stand for about 10 or 15 minutes before percolation commences. The pregnant solution flows to the precipitating department. After about 2½ hours of percolation the charge receives a water-wash for ½ hour, after which the tailing is discharged by rotating the barrel.

The amount of wash water used is only sufficient to counterbalance the loss of that quantity of mill solution used to moisten the ore, plus that evaporated from the towers and tanks. As the metals go into solution very rapidly they are removed from the gangue early in the period of percolation. The solution applied toward the end of the period is practically a barren wash, and the final wash with water serves mainly to recover salt. Enough water remains with the tailing to make it flow like thick molasses when discharged from the barrels. No fouling of solution takes place, as it is renewed practically every day. Iron does not go into solution to any great extent, and even when treating oxidized ores high in iron the pregnant solution will contain but 0.1 per cent of that metal.

If much gold is present in the ore it is considered necessary to have the mill solution stronger in chlorine, and that element must be added in some form or other. Manganese dioxide existing naturally in the ore, or added as a constituent of the roaster feed, would generate chlorine by reaction with the chlorides present.

### Precipitation on Metals and by Electrolysis

The gold, silver and copper in the pregnant solution are precipitated successively on more electro-positive metals—silver and gold on copper, and copper on lead. The final lead solution is electrolyzed under high current density. Precipitation is accomplished in revolving wooden drums, or wood-lined trommels, containing the necessary metals in the form of small spheres. The metal precipitated in one drum is removed by settlement or filtration before the solution flows to the next drum. This method of precipitation is continuous, rapid and highly efficient, as the solution is warm and the surface of the precipitating metal is constantly kept clean by abrasion. The electrolysis of the lead solution yields a spongy product which is made compact by rolling before it is melted. The acid gases from electrolysis are conducted to the towers where, together with the roaster gases, they are absorbed in the barren mill solution that comes from the precipitation department.

The metallic products are high grade, and after melting are ready for market. Some of the copper and lead can be converted into suitable forms for precipitating purposes, and the accumulating balance can be disposed of in the market.

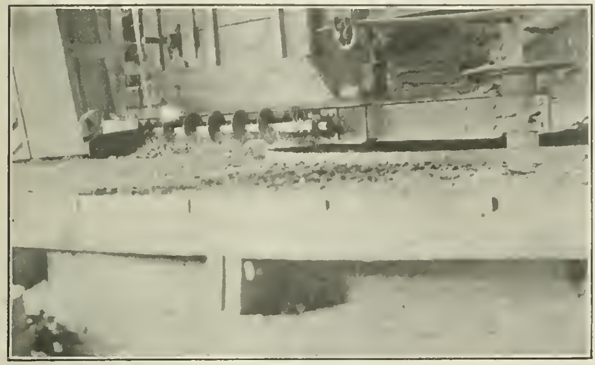

FIG. 4—CHLORIDIZING FURNACE, KNIGHT-CHRISTENSEN MILL

Wooden pipes and rubber hose are used for the transportation of the mill solution. There are no valves and no pumps in the system. All elevating of solution is done by means of wooden montejus. Porcelain pumps could be used successfully under a low head, and probably would be adopted in a new plant. Some porcelain pipe also could be used to advantage, as wooden pipe does not swell under the action of salt solution as with water, and is likely to permit some leakage.

While this mill of the Knight-Christensen Metallurgical Co. is regarded as an experimental plant on a large scale, nevertheless its sponsors are satisfied that they have demonstrated a process that will be profitable. Another mill employing the same methods and apparatus is expected to be in operation in the Park City district in the near future, and we hope later to present some data thereon.

---

## The Effects of Pickling Upon the Corrosion of Iron

BY E. A. RICHARDSON

In connection with a test that was to be made upon the corrosion of sheet iron, the question arose as to how the surfaces should be cleaned. Since a number of methods could be used, it was necessary to know what effect these different methods would have on the subsequent corrosion. A small preliminary test of short duration was, therefore, made to determine the best method for cleaning the specimens to be used in the larger test.

In much of the literature that deals with the corrosion of iron and steel, little mention is made of the method of preparing the samples for test, that is, little attention seems to have been given to the means of eliminating the effects of scale on the specimens of sheet metal and in particular to the effect produced when this scale is removed by pickling.

It is the object of this article to show that for short time tests the effect of pickling exerts a great influence upon the rate of corrosion, and that tests in which this effect is not eliminated are not comparable and may even be unreliable and misleading.

This conclusion is based upon the results of a test made upon four kinds of commercial sheet irons. The samples tested were 16 gauge in thickness and 4 in. square. In order that they might be comparable before pickling, they were annealed in a muffle furnace at the same time at a temperature of 750 deg. C. and cooled slowly.

The samples were pickled as follows:

(1) Scale removed by grinding on an emery wheel,
(2) Scale removed by pickling in sulphuric acid,
(3) Scale removed by pickling in sulphuric acid, and the samples washed in water and dipped in dilute nitric acid.
(4) Scale removed with sulphuric acid and the samples washed with water and dipped in a mixture of ammonia water and hydrogen peroxide.

After pickling, the test pieces were washed thoroughly with water and dried by dipping in alcohol. They were then measured and weighed and exposed to the weather in a wooden rack from October 1 to January 1.

The four materials used analyzed as follows:

| Sample | Sulphur | Phosphorus | Carbon | Manganese | Copper |
|---|---|---|---|---|---|
| a | 0.020 | 0.003 | 0.01 | 0.052 | 0.048 |
| b | 0.059 | 0.117 | 0.10 | 0.319 | 0.268 |
| c | 0.045 | 0.094 | 0.10 | 0.406 | Trace |
| d | 0.051 | 0.009 | 0.035 | 0.044 | 0.044 |

It was noticed at once that the method of pickling had a decided influence upon the starting of corrosion. The samples which had been dipped in nitric acid were the last to start rusting; in fact they were rained upon several times before any signs of rusting appeared. The others started to rust after the first rain.

The duration of this test was ninety-five days, after which the samples were examined before removing from the rack, the examination being made by three independent observers. All three agreed to the same classification, which was as follows:

First. Sample "b." This material was by far the best. The rust was red in color and adherent and was smooth and fine grained.

Second and Third. Samples "a" and "d." These materials were corroded about equally. The rust was coarse-grained and was becoming loose.

Fourth. Sample "c." This material was much the worst. The rust was yellow in color, was coarse-grained and very loose.

After cleaning the surface of the samples with neutral ammonium citrate solution, the same three observers again observed them. The results were as before.

After these inspections the samples were reweighed and the loss in weight computed in grains per square centimeter. The results are as follows, each figure being an average of two:

METHOD OF CLEANING SURFACE

| Sample | Grinding | Sulphuric acid | Sulphuric and nitric acids | Sulphuric acid and ammonia and peroxide |
|---|---|---|---|---|
| b | 0.0372 | 0.0420 | 0.0293 | 0.0389 |
| a | 0.0597 | 0.0600 | 0.0441 | 0.0512 |
| d | 0.0651 | 0.0463 | 0.0497 | 0.0476 |
| c | 0.0952 | 0.0967 | 0.0646 | 0.0864 |

From an examination of the above figures it is evident that the method of cleaning the surface of test pieces before exposure has a decided influence upon the rate of corrosion. This is particularly noticeable when a passifying agent such as nitric acid is used. Upon long exposure tests this effect would undoubtedly be decreased and might perhaps be eliminated.

The author acknowledges several suggestions made by Mr. L. T. Richardson during the progress of this test.

Warren, Ohio.

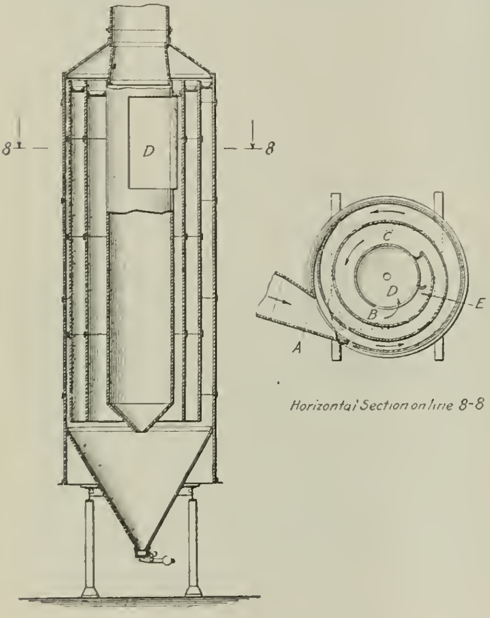
# The Gas from Blast Furnaces, Its Cleaning and Utilization

BY J. E. JOHNSON, JR.

(Concluded from p. 692.)

### PRIMARY WET CLEANING

For primary cleaning, in Europe in particular, a separation of the dust by the use of water has been preferred for many years to a dry separation, on account of the very much greater efficiency obtained in cleaning, and on account of the importance of reducing the water vapor contents of the gas to a minimum, thus allowing more efficient combustion. The cooling and washing of the gas are usually performed simultaneously, sufficient water being used to reduce the temperature of the outgoing gases to practically the temperature of the incoming wash water. Experience has shown that cooling the gas in this manner, to allow condensation and separation of the water vapor, causes less attendant loss of heating efficiency than prevails in heating with vapor-laden gas.



FIGS. 11 AND 12—DYBLIE WHIRLER

### ZSCHOCKE SYSTEM

Zschocke washers have been used almost entirely in Germany for wet primary cleaning. These consist of cylindrical or square steel towers fitted with a series of wooden grids or hurdles placed at suitable intervals within the apparatus. These hurdles are arranged in such a manner that the water, which is sprayed in at the top of the tower, is broken up into very fine streams, which drip down between the grids and meet the gas coming up, the gas being introduced at the bottom of the tower. The intimate contact so obtained wets down the dust, which is carried with the water to the bottom. These Zschocke towers are usually water-sealed and cone-shaped at the bottom, and the latest type has a siphon arrangement; in either case, the dust is readily removed from the bottom of the apparatus.

Zschocke towers have been found sufficient to cool and clean the gas to the proper degree for use in hot-blast stoves, under boilers, and for similar purposes. A fan washer, into which water is introduced, is frequently used as an auxiliary to the Zschoke towers for primary cleaning, especially when the scrubbing capacity of the towers is small.

A water separator, equipped with internal baffles, is usually located beyond the washer to allow separation of the entrained water.

Zschocke washers are used considerably in the United States, and some additional systems have also been developed here for the wet separation of dust; for instance, the Duquesne spray tower and the Steinbart spray tower. The basic principle of these spray towers consists of the creation of a rain or spray by means of suitably arranged nozzles, and the gas is cleaned and cooled in passing through this spray.

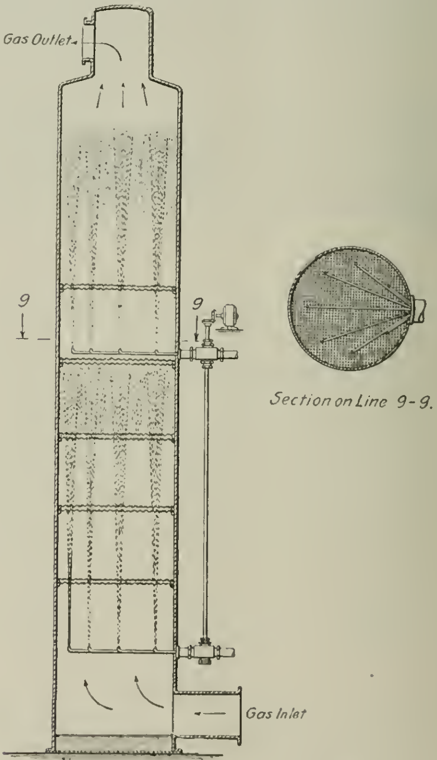


FIG. 13—DUQUESNE SPRAY TOWER

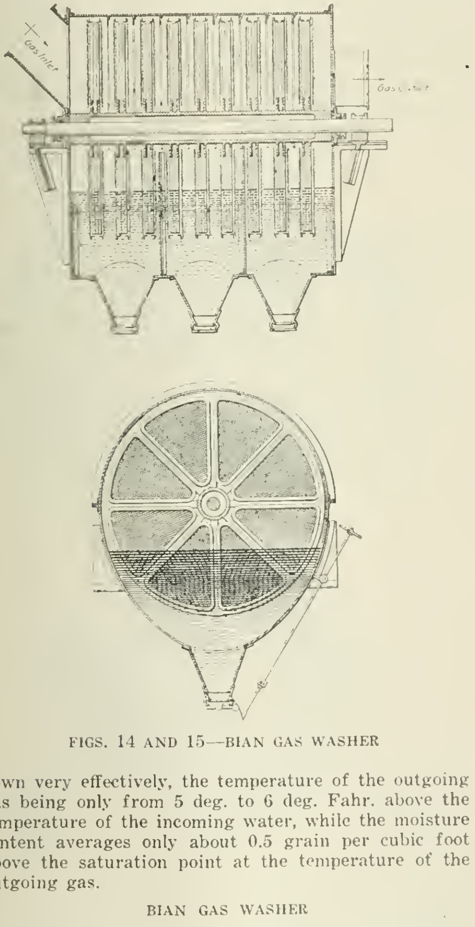
### DUQUESNE SPRAY TOWER

The Duquesne tower consists of a shell about 80 ft. high by 12 ft. in diameter. As shown in Fig. 13, the tower contains five sets of double screens, the sets being spaced 6 ft. 10 in. apart. Under the first set of screens are distributed seven nozzles, the feed water for which is controlled by a valve outside the tower. Under the fifth set of screens, seven similar nozzles, also controlled by a valve outside the tower, are distributed, just above the range of the lower nozzles.

The controlling valves have a revolving core which successively blocks off the openings to the different nozzles, thereby temporarily stopping the flow of water and creating an area of low pressure directly above the nozzle. When the core has passed, the flow of water resumes through this nozzle and sprays the gas which has reached this point. The core is revolved electrically, at the rate of about 15 revolutions per minute, and a 5-hp motor is ample to operate four valves, which are sufficient for two towers.

The screens, which are placed above the nozzles, break up the water into fine drops, permitting intimate contact of the gas and the water.

In the operation of these towers at Duquesne, the gas rises through the scrubber at the rate of 4 ft. per second, and the water at the rate of 60 ft. per second with a head of 35 lb. main pressure. The gas is cooled down very effectively, the temperature of the outgoing gas being only from 5 deg. to 6 deg. Fahr. above the temperature of the incoming water, while the moisture content averages only about 0.5 grain per cubic foot above the saturation point at the temperature of the outgoing gas.



FIGS. 14 AND 15—BIAN GAS WASHER

### BIAN GAS WASHER

The Bian gas washer, as shown in Figs. 14 and 15, consists of a stationary horizontal steel cylinder through which the gas passes from one end to the other. Inside the cylinder, there slowly revolves a shaft which carries a number of vertical disks consisting of wire netting of fine mesh. The diameter of these disks is very slightly less than the inside diameter of the cylinder, and this arrangement necessitates the gas passing through the openings in the screens as it travels through the apparatus. The screens, to the extent of nearly half their diameter, dip into water contained in a trough upon which the open bottom of the cylinder rests, and as the shaft revolves, the part of the screens which has been immersed rises from the water with the meshes covered with thin films of water, thus allowing thorough contact with the gas as it passes through the perforations.

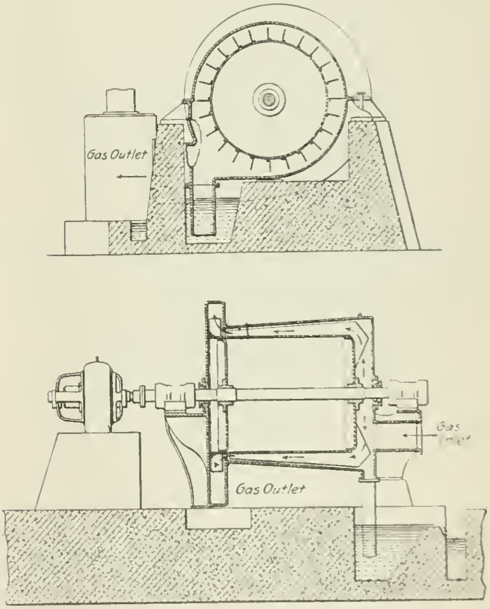
### FINAL WET CLEANING

(Some of these systems can also be applied to primary cleaning.)

The amount of cleaning accomplished in Zschocke and similar towers, and in the Bian washer, while satisfactory for stoves and boilers, was found to be not sufficient when the gas was destined for use in gas engines, and the systems of Theisen and Schiele were developed for this purpose.

### THEISEN GAS WASHER

The Theisen washer, as shown in Figs. 16 and 17, consists of a casing lined with a special wire netting, within which revolves at a high speed, a drum carrying numerous fan blades set at oblique angles to the axis of rotation, these blades or vanes being so fitted that they form a continuous spiral curve. This allows the gas to be drawn in at one end of the casing and expelled at the other end. Water is admitted at the side of the casing and is converted into a fine spray by the revolutions of the blades, and the spiral arrangement of these blades causes the spray to flow in the opposite direction to the gas, which passes through this spray, being simultaneously cleaned and cooled. The dirty water leaves the apparatus by a water seal at the bottom.



FIGS. 16 AND 17—THEISEN GAS WASHER

The Theisen and Schiele systems of final wet cleaning have for years given very satisfactory results, but are now being gradually superseded by systems requiring less capital expenditure and less operating expense. Most of these systems can be used for primary cleaning as well as for final cleaning, by installing in two stages. The most important of the wet cleaning systems which perform as efficient cleaning with the consumption of much less power and water than the Theisen and Schiele systems are the disintegrator system of Theisen, the disintegrator system of Schwarz-Bayer, the Fowler & Medley rotary washer, and the Feld rotary washer, while the Halberger-Beth dry cleaning system of filtration through canvas is remarkably efficient in cleaning and is cheap to operate. Following is a detailed description of each of the systems mentioned, together with several other modern systems:

### THEISEN DISINTEGRATOR GAS WASHER

There are two styles of Theisen disintegrator gas washers. One style consists of a casing in which the gas enters by two apertures at the base of the apparatus and is washed by a spray of water in a perforated drum or cage equipped with vanes, the drum revolving within a stationary drum, the gas being drawn through the apparatus by a fan mounted on the same shaft and discharged with the necessary pressure to carry it to the point of consumption. The second style also has the fan mounted on the shaft, but the fan is inclosed within the disintegrator.

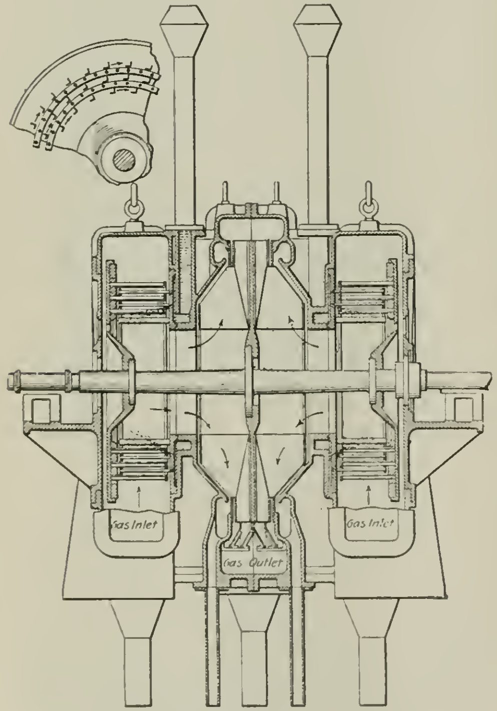


FIG. 18—THEISEN DISINTEGRATOR GAS WASHER

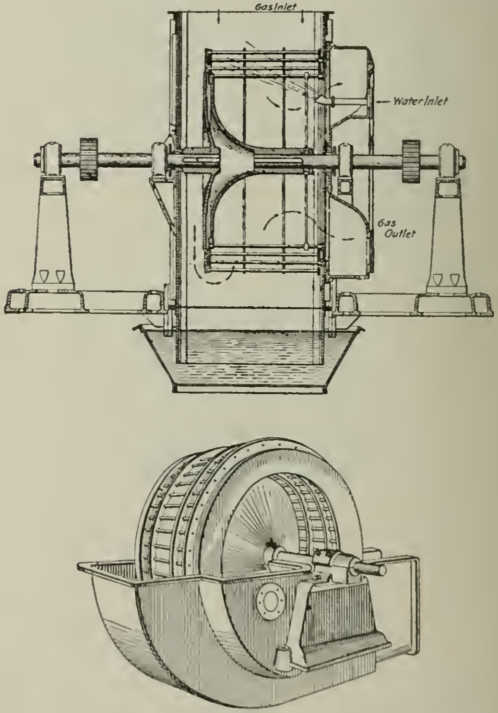
The Theisen disintegrator consists of a series of rotary and stationary perforated drums or cages arranged concentrically within one another, as shown in Fig. 18. The stationary drums consists of round bars and the revolving ones of angle bars. The hot raw gas enters the apparatus at the bottom, meets the effluent water and undergoes a preliminary cooling and cleaning in the lower part of the machine. The gas is drawn in counter-current through the series of rotary and stationary drums by means of a fan. The water is converted into a fine spray by the centrifugal action of the rotating drums, and the gas, passing through this spray, is cleaned. The fan is located in the same casing and on the same shaft as the rotary disintegrating drums, the shaft being direct motor driven. Fresh water is introduced into the innermost rotating drums in the form of a finely divided spray.

The cooling and cleaning of the gas and production of the pressure necessary to conduct the clean gas to its point of consumption are all performed in one apparatus and with one motor. It is stated that this disintegrator is an improvement over the former. Theisen apparatus, requiring much less power and water, and performing the necessary cleaning of the gas without preliminary towers.

### SCHWARZ-BAYER DISINTEGRATOR GAS WASHER

The Schwarz-Bayer system of gas cleaning makes use of the disintegrator principle, and its general arrangement is simple. The complete set of gas-cleaning apparatus consists of a disintegrator in connection with a saturating chamber in the form of a hood; then a fan placed immediately behind the disintegrator, and finally a water separator. In case both primary and final cleaning are desired, two such sets of apparatus are used, the second of which further cleans the gas which has been primarily cleaned in the first.



FIGS. 19 AND 20—SCHWARZ-BAYER DISINTEGRATOR GAS WASHER

The disintegrator, as shown in Figs. 19 and 20, consists substantially of two sets of steel pins, cold-riveted to two steel disks, which disks are set side by side and revolve in opposite directions. The pins of one revolving disk, which interlace with the pins of the other revolving disk, form with the water, through the effect of rotation and dripping, a fine spray or mist, which allows a thorough mixture of the water with the gas traveling among and between the pins before leaving the apparatus.

The gases from the blast furnace pass from the raw gas mains directly into the disintegrators without previously passing through Zschocke towers or similar preliminary washer or cooler. The gas enters through the top of the hood and passes toward the center of the disintegrator, while water is being introduced through the sides to the center. The hood acts to some extent as a pre-cleaner and cooler, as some of the spray from the disintegrators is thrown into the hood and there comes in contact with the hot gas and rapidly evaporates, simultaneously cooling the gas. By the revolution of the disintegrator the water is projected toward the periphery of the apparatus and is broken up into a fine spray; the gas mixes thoroughly with this water and is cooled, and most of the dust contained in the gas is precipitated. The gases pass through the disintegrator in a current counter to that of the water.

The application of the counter-current principle enables the gas to encounter cleaner and colder water in its passage through the disintegrator; hence it is better cleaned, and its temperature is reduced more nearly to the temperature of the entering cooling water. This principle has the effect of materially reducing the amount of water and power consumed. Each disk is direct driven by an individual motor and the speed is determined by the degree of cleanliness desired in the gas. The gas is drawn through the disintegrator by means of a fan located immediately behind the disintegrator apparatus, and passes from the fan to a water separator.

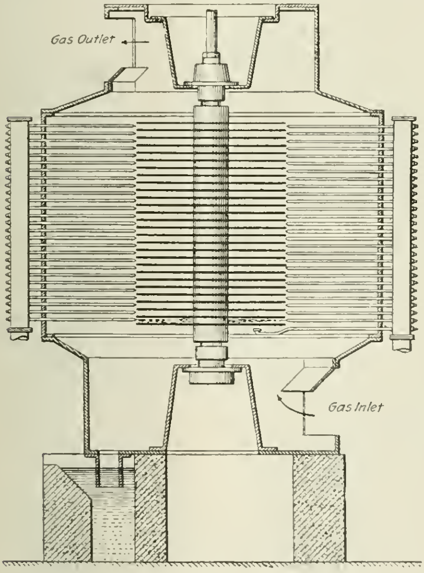


FIG. 21—FOWLER & MEDLEY VERTICAL GAS WASHER

The use of pins in this apparatus as a disintegrating medium allows the passage of the gas with very little resistance, and a consequent saving in power. There is also very little possibility of the dust settling on the pins and clogging up the apparatus.

### FOWLER & MEDLEY VERTICAL GAS WASHER

This apparatus, as shown in Fig. 21, consists of a circular cast-iron casing containing a revolving shaft running vertically through the middle. On this shaft are fixed a number of disks, made either of steel or of cast iron, depending upon whether the water used is alkaline or acid. Each disk is equipped with a collar separating it from the adjoining disks, and each collar is punched or drilled with six holes, through which six bolts pass vertically, thus holding all the disks in place. The shaft is direct driven with a vertical-spindle motor. Two fixed water sprays are provided for each disk, diametrically opposite each other, one on each side of the washer and projecting between each pair of disks. The jets of water, which are introduced through nozzles having about $\frac{1}{8}$-in. openings, enter with sufficient pressure to strike the collar between the disks, and, as the disks revolve, the water is thrown against the top and bottom of these disks and then against the outside wall of the casing, creating a fine spray or mist in the space between the outer edge of the disk and the wall of the casing, through which space the gas passes. The gas enters the washer at the bottom, passes through this spray or mist, and leaves clean at the top.

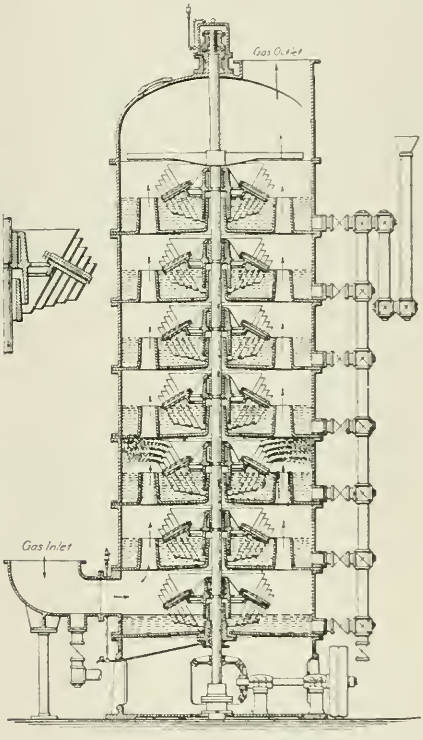

FIG. 22—FELD GAS WASHER

This washer can be used for either primary cleaning or final cleaning, or both; in case final cleaning is desired, two washers would be used in series, the first apparatus to clean the gas sufficiently for primary purposes and the second apparatus to finish the cleaning of the gas for gas-engine use.

### FELD GAS WASHER

The Feld washer, as shown in Fig. 22, consists of a series of superimposed sections, the bottom of each section being provided with ports for the passage of gas. The gas enters the bottom of the washer and passes from chamber to chamber to the top, whence it is led away. Each section or chamber is provided with a series of cones perforated at the top and mounted upon a cast-iron spider, which is carried on a vertical shaft. The shaft is suspended at the top in a specially designed anti-friction bearing, arranged so as to reduce the power required for operation to a minimum. The water is admitted into the top of the washer and overflows from section to section through the gas ports, the dirty water saturated with dust leaving the bottom of the washer.

When the shaft revolves, the cones do likewise, and the water is raised by centrifugal force along the inner sides of the cones and is atomized at the upper edge. This upper edge of each cone is a little higher than the next outer one, thereby forming a certain number of horizontal sprays of water, depending on the number of cones. The upper portion of the outer cone, which is somewhat higher than the inner one, is perforated. The inner cones supply water to the perforated surface of the outer one. This results in the formation of a series of cascades composed of very small drops of water, through which the gas must pass en route through the apparatus.

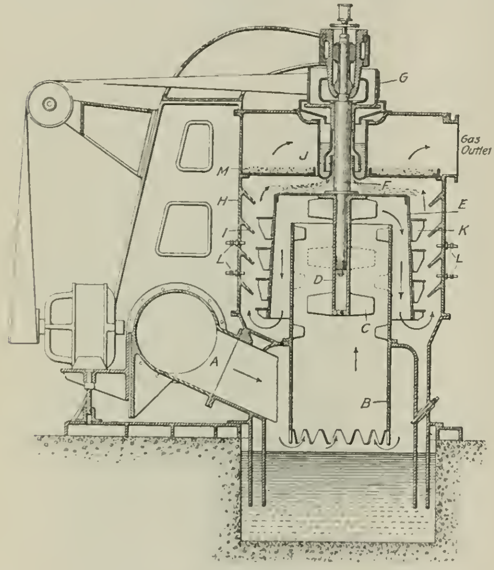

FIG. 23—RECO CENTRIFUGAL GAS WASHER

The washing is accomplished mostly in the lower sections, while the upper sections perform primarily the function of cooling the gas.

For primary washing, the Feld washer is constructed with seven chambers or sections, the lower three being the washing chambers, the fourth one being a separating chamber and the upper three being the cooling chambers. For final washing, in the case of the gas being required for gas-engine purposes, the gas after being primarily cleaned is passed through an additional washer of the same general arrangement.

### RECO CENTRIFUGAL GAS WASHER

This gas washer is constructed by the Roessing-Ernest Company, of Pittsburgh, Pa., and is designed to cool, clean and, if necessary, dry the gas in one apparatus. This washer consists substantially of a vertical outer casing, a tube whose lower end is provided with serrations extending to within a few inches of a water seal, a revolving inverted cup, and a sleeve casing attached to the inverted cup. The outer casing, the cup, the tube, and the sleeve casing are provided with shelves and vanes. The apparatus is belt-driven. The spindle of the rotor on which the driving pulley is fastened is hollow, and the weight of the rotor is taken up by the shaft inside of this sleeve held by a ball bearing which is backed by a rubber buffer in order to equalize any irregularity during rotation.

As shown in Fig. 23, the hot gas enters the apparatus at the point *A*, passes over the water, a certain amount of which the gas takes up by evaporation, and then passes into the tube *B* through the serrations at its base. During its passage through this tube the gas and water vapor are subjected to a thorough beating and mixing by the action of the vanes *C* of the revolving sleeve casing *D*, fastened to the top of the inverted cup *E*. The gas passes into this inverted cup, which is rotated by the driving sleeve *F* and the pulley *G*, and then flows downward, around and under the lower edge of the cup and then upward between the cup and the outer casing *H*. The outer surface of the revolving cup is provided with concentric shelves *K* and the outer casing *H* is provided with downwardly inclined shelves *I*, which receive the washing water from the water-sealed stuffing box *J* and through a series of water pipes *L*. The water, falling on the rapidly rotating shelves of the cup, is thrown by centrifugal force against the inner walls of the casing and thence flows downwardly along the inclined shelves, dripping on to the next rotating shelf, and so on. In this way the gas, while subjected to a thorough whirling and beating action, has to pass upward through several films of finely divided water or spray while the water passes downward, carrying with it the separated impurities.

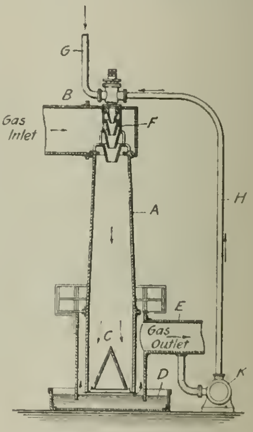

FIG. 24—SEPULCHRE GAS WASHER

The apparatus operates on the counter-current principle, the cleanest gas passing from the apparatus meeting the cleanest water entering the apparatus.

The upper part of the casing is provided with a rack which, it is stated, can be packed with suitable drying material in case it is desired to dry the gas before leaving the apparatus.

### SEPULCHRE GAS WASHER

This system is designed as a final washer to further clean primarily cleaned and cooled gas to the degree necessary for use in gas engines. The principle of this system consists in creating in a vertical tower a very fine spray or mist of water by means of an injector of the Körting type, in which water under pressure is atomized by means of compressed blast-furnace gas, the spray being produced by the expansion of the compressed gas. An intimate mixture of the spray so formed, with the dirty gas entering the apparatus, is obtained by the arrangement of the apparatus.

A separator is provided in connection with this apparatus, which consists substantially of a cone arranged in the lower part of the tower in such a way as to leave between the base of the cone and the walls of the tower a very narrow passage, through which the gases are forced over the surface of a water seal, where the dust and water vapor are deposited.

In the accompanying drawing, Fig. 24, *A* is the vertical tower, the lower end of which terminates a short distance above the surface of the water seal *D*. Within the lower end of the tower is arranged a conical deflector, *C*, and near the top of the tower is the gas inlet, *B*. The lower section of the tower *A* is surrounded by a casing which is open at the bottom and extends beneath the surface of the water in the seal.

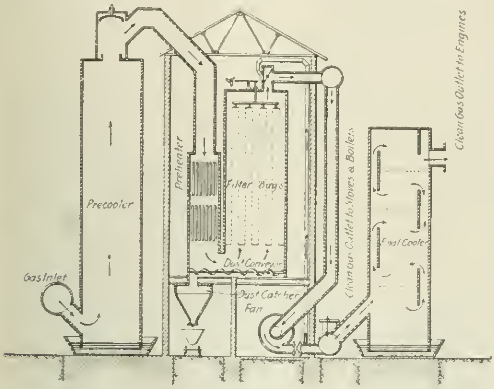

FIG. 25—HALBERGER-BETH GAS-CLEANING SYSTEM

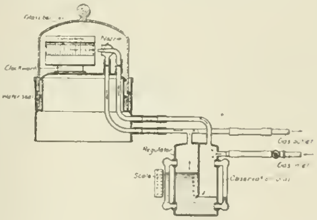
A gas outlet, *E*, is provided in connection with the outer casing. The Körting injector is located at *F* and the feed water for same is supplied through the pipe *G*. The pressure is supplied by withdrawing a portion of the purified gas from the outlet pipe *E* and forcing this by the compressor *K* through the pipe *H* into the injector simultaneously with a stream of water.



### FINAL DRY CLEANING

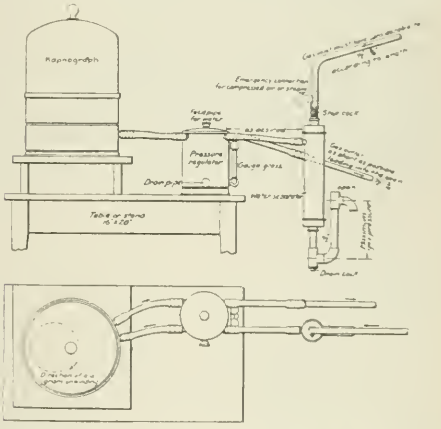
(Some of these systems can also be applied to primary cleaning.)

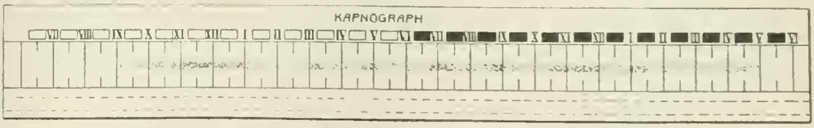
### HALBERGER - BETH GAS-CLEANING SYSTEM

The principle of the Halberger-Beth system, shown in Fig. 25, is based primarily on filtering the gas through canvas bags. The gas coming from the blast furnace passes through the usual dust catchers and gas mains to a cooling tower, where the temperature of the gas is reduced to about 175 deg. Fahr. The cooling tower is arranged so that the necessary amount of cooling can be accomplished either by air or by direct contact with water, depending on the temperature of the gas entering the cooler, which temperature is naturally variable, in accordance with blast-furnace conditions.

From the cooler, the raw gas, by means of the suction of a fan placed beyond the filters, or without a fan when the pressure of the gas issuing from the furnace is sufficient, passes into and through the canvas filtering bags, depositing its impurities on the surface of the bags. These canvas filters are contained in a series of double compartments, each usually holding twelve canvas bags in rows of three by four. Each bag is about 8 in. in diameter by 9 ft. 9 in. long, and is equipped with a ring at each 18 in. of its length to prevent entire collapse of the bag when cleaning. The bags are fastened into a stationary header at the bottom, this bottom end being open, while the top is closed by a steel plate. Each bag is connected with a shaking mechanism located outside and above the filter compartment, and at regular intervals, usually about every four minutes, these bags are automatically shaken, a compartment at a time, for a period of from fifteen to twenty seconds. By means of a butterfly valve, the uncleaned gas is shut off from the compartment while the shaking is in progress, and cleaned gas, superheated to the proper temperature of about 175 deg. Fahr., is forced under pressure into the compartment. This causes a partial collapse of the canvas bags, which, in conjunction with the simultaneous shaking, allows the dust to fall from the canvas. The separated dust drops into a hopper beneath the sacks, whence it is transferred by means of a spiral conveyor to a bin, from which it is loaded into cars. At the end of the cleaning period the butterfly valve automatically returns to its original position and filtering commences again.

It is quite necessary to keep the temperature of the gas at about 175 deg. Fahr., as if much higher than this there is danger of scorching the bag, while if lower the water vapor in the gas is deposited on the canvas and prevents proper filtration. In case the gas becomes cooled below 175 deg. Fahr. in the cooling tower, it is superheated by means of steam or by waste heat from the hot-blast stoves to about this temperature before entering the filtering bags. After leaving the canvas bags, the gas requires no further cleaning





*Specimen of strip indicating one days run at a European Gas Engine Plant*

FIG. 29—THE KAPNOGRAPH

for gas engines and is cooled down to the proper temperature in cooling towers of various designs.

The degree of cleanliness of the gas is indicated by the clearness of the effluent water from these towers and no settling basins are required. Consequently, this water can be used over and over again, which is a material item in districts where water is scarce. A further advantage lies in the non-pollution of streams, the laws relating to which are very strict in certain districts.

This system utilizes the basic principle employed in the "bag house" system, which has been used for the last twenty years in connection with recovering zinc dust from the gas issuing from zinc oxide furnaces and collecting dust from lead smelters.

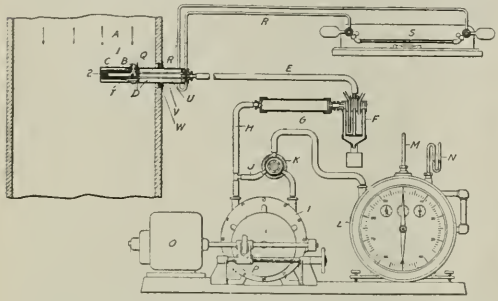


FIG. 30—THE BROWN DUST, MOISTURE AND VOLUME DETERMINATOR

THE KAPNOGRAPH

This instrument, shown in Fig. 29, continuously indicates the relative degree of cleanliness of the blast-furnace gas going to the gas engines, and is extensively used in European gas-engine stations. Gas from the cleaned gas main passes through this apparatus and impinges upon a continuous recording chart, upon which the dust in the gas is deposited. The variations in the amount of dust in the gas are indicated by lighter or darker shades on the recording paper, depending on the amount of dust deposited. The flow of gas to the instrument is maintained either by the natural pressure of the gas, or, if this is not sufficient, by an aspirator behind the outlet pipe. The speed of the gas to the nozzle is kept constant by means of a regulator, as shown in sketch, the excess gas over the required amount escaping into the outlet pipe by passing under a partition and through a seal of water.

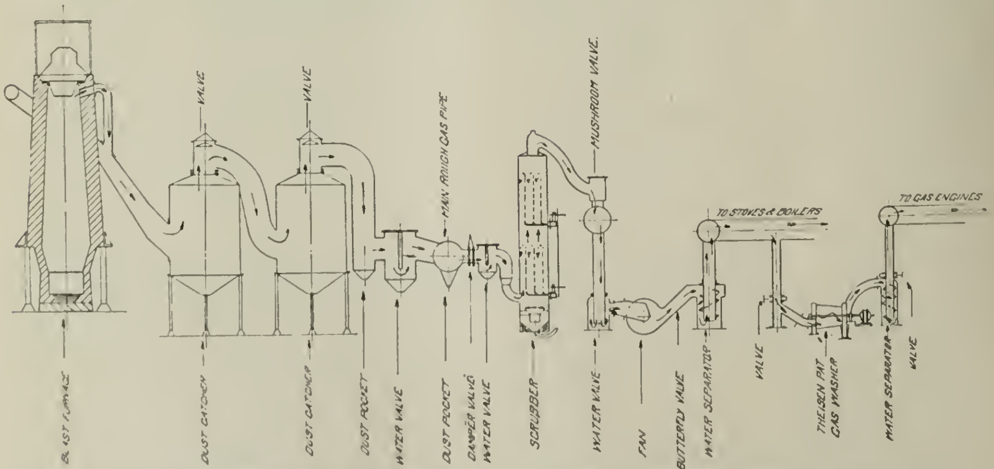

FIG. 32—THE COURSE OF THE GAS THROUGH THE CLEANING PROCESSES TO STOVES, BOILERS AND ENGINES

METHODS OF DETERMINING THE AMOUNT OF DUST IN BLAST-FURNACE GAS

A method employed with good results in Europe for determining the amount of dust in the gas consists in drawing a definite quantity of the blast-furnace gas to be tested through a filter, which is weighed in a dry condition before and after the test. The apparatus for determining the amount of dust consists of a glass tube drawn out at one end and fitted at the other with a ground-glass cover which is also drawn out to a thin tube. This cover facilitates the placing of the filtering material in the tube, and during the test the cover is fastened to the tube by means of wire. Before the test, the glass tube, filled with suitable filtering material, is placed in a drying furnace and heated at a tem-

perature of 105 deg. C. until its weight is constant, which usually requires from one to two hours. The drying furnace is arranged so that several tubes can be dried simultaneously.

During the drying process air is drawn through the tubes after having previously been thoroughly dried by passing through bottles containing calcium chloride and concentrated sulphuric acid. During the drying process the tubes are weighed until no further increase in weight is observed.

In making the test, the weighed tube containing its filtering material is inserted into the gas main, a rubber stopper keeping the test-hole tight. The upper end of the tube is connected with a gas meter, which in turn is connected with a barrel filled with water. The water is allowed to flow out of the barrel and in so doing creates the necessary suction to draw the gas through the filtering tube and through the gas meter. When the necessary amount of gas has beën withdrawn the tube is again dried and weighed. The increase in weight indicates the amount of dust in the quantity of gas tested.

## BROWN DUST, MOISTURE, AND VOLUME DETERMINATOR FOR BLAST-FURNACE AND OTHER GASES

This apparatus has been devised in order to accurately determine the amount of dust and moisture contained in blast-furnace gas, as well as the volume of the gas, and is used iwth considerable success.

Referring to the accompanying drawing, Fig. 30, *A* is a gas main conveying the gas to be tested. *B* is an aperture in the small pipe through which samples of the gas are drawn. *C* is a filtering medium within which the solid constituents of the gas are deposited. *D* is a conduit leading to the exterior of the gas main through which the filtered gas is conducted. *E* represents a flexible connection to a surface condenser, *F*. *G* represents a receptacle for some chemical, such as calcium chloride, which can be used for the purpose of taking out the moisture contained in the sample. *H* is a conduit from this moisture-removing receptacle to the rotary air pump, *I*, or through the by-pass *J* to the three-way valve *K* and thence to the gas meter *L*, where the volume of the sample is determined, together with its temperature and pressure; these latter by means of the thermometer *M* and the U-tube *N*, respectively. An electric motor, *O*, is used to operate the pump *I* through the variable-speed drive *P*.

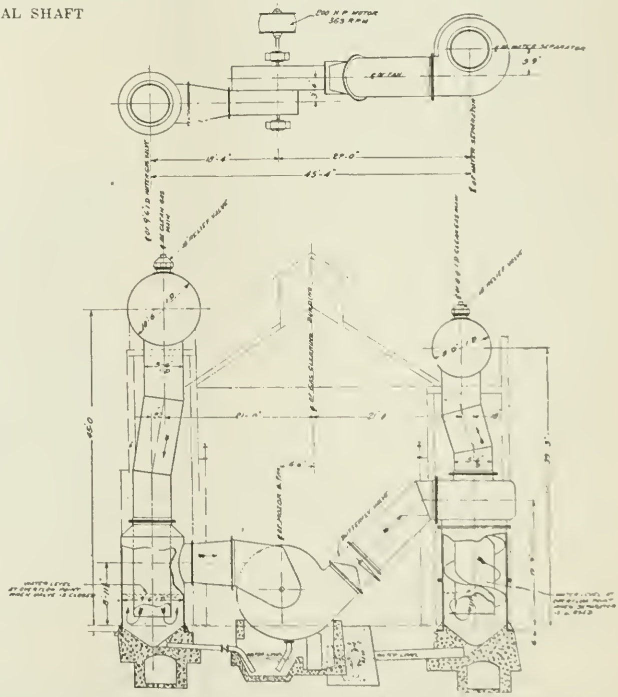

FIG. 34—SECTION THROUGH FANS, AND METHOD OF PASSING GAS THROUGH SEALS AND SEPARATORS

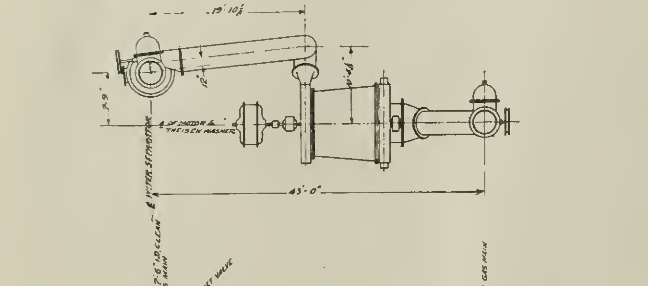

FIG. 35—SECTION THROUGH THEISENS, SEALS AND SEPARATORS

An indication of the velocity of gas or gases in conduit *A* is transmitted through aperture *Q* in the sample pipe and conduit *R* to horizontal pressure gauge *S*; also an indication of the velocity of gas or gases after passing aperture *B* is transmitted from aperture *T* through conduit *U* to horizontal pressure gauge *S*. It is evident that changes of the velocity of the gas or gases in aperture *B* of sample pipe, produced by the suction of pump *I* or by pressure in gas main *A*, are indicated, and can be accurately controlled and made equal to the velocity of the gas or gases in conduit *A*, the gas main, such indicator being the oil piston shown in glass tube forming a part of the velocity gauge *S*.

The method of operating this apparatus is as follows: The dry weights of the filtering medium *C*, of the receptacle *G*, containing the calcium chloride, and of the measuring flask attached to surface condenser *F*, are very carefully determined. They are then inserted in the apparatus, and the sample pipe is then inserted in the gas main, a tight connection being made between flange *W* and bushing *V*. The meter reading is noted. At the same time that the sample pipe is inserted in the gas main *A*, the time is noted, and the rotary pump *I* started. The speed is then so regulated that the oil piston in the horizontal pressure gauge *S* is maintained in equilibrium. This indicates that the velocity in aperture *B* is exactly equal to the velocity in gas main *A*, this condition having been determined by a measured amount of gas in gas main *A*, and the proper proportioning of aperture and conduits in the sample pipe during the calibration tests. This condition is maintained for an indefinite length of time and the sample pipe is then withdrawn from gas main *A*. The meter reading, multiplied by the ratio of area of aperture *B* to area of gas main *A*, gives the total amount of gas passing through gas main *A* in the elapsed time. The difference between the dry weight of the filtering medium *C*, before and after the test, divided by the number of cubic units shown by the meter, gives the weight of dust per cubic unit. The moisture per cubic unit of gas is found in a similar manner from the sum of the weights of the water in drying receptacle *G*, the water caught in the measuring flask attached to surface condenser *F*, and the weight of water retained in the filtering medium *C*.

Figs. 31 to 36 are reproduced from Mr. Diehl's paper as showing approved types of construction. The text of Mr. Diehl's concerns itself principally with operation and will be quoted in dealing with that subject.

In addition to the processes so clearly described by Mr. Forbes, there are various others designed to remove the dust from the gas in the dry state, but as these have had no extensive application for the blast furnace process, they may be omitted here.

Even since the time of Mr. Forbes' paper there has been an extensive development in Europe of the Halberger-Beth process of which there are now almost thirty plants in use in Europe and the number has been rapidly increasing. American furnacemen have been slow to take up this process and have acted in this matter along the same line as in many other cases; where an apparatus requires careful supervision or where its maintenance charges are high, operating economies secured by its use are disregarded. The same has been true in regard to the gas engine, by-product coke-oven and many other kinds of apparatus.

FIG. 36—DIRTY-GAS MAIN WITH CLEAN-GAS MAIN AT HIGHER LEVEL, ALSO THE END OF THE REFINED-GAS MAIN LEADING FROM THE THEISENS TO THE ENGINES

This attitude is one often censured not only by foreigners, but also by Americans who do not consider all the aspects of such problems, particularly the financial one. The relative cheapness of capital and supervision and the costliness of raw materials in Europe as contrasted with the high cost of capital and supervision in America and the low cost of raw material constitute in no small measure a justification for the American attitude.

There is reason to hope that a process may soon be developed superior to either the wet processes or bag filtration plant and less complicated and difficult of maintenance. I refer to the Cottrell process for the electrical precipitation of the dust by a high-tension direct current passing through the gas column. This process has been developed to complete success in several lines of industry but its sponsors have hesitated to attack the blast furnace problem on account of its size and the complexity of the conditions. If this process shall ever be worked out to a commercial success it will furnish gas absolutely clean with no loss of temperature and with no increase in its moisture. These are the ideal conditions for the use of furnace gas for combustion purposes. For the gas engine it must in any event in present practice be cooled about to atmospheric temperature and this, of course, can easily be done after the gas is removed by a direct spray. Perhaps the time might even come if hot cleaned gas were available that the gas engine could be adapted to its use and thereby further increase its economy.

In conclusion it may be said that it is impossible at the present time to write a history of gas cleaning. The whole development of the subject in this country covers barely ten years in all and nine-tenths of it has been in the last seven or eight years. The advantages have become manifest and all furnacemen have sought *a* way rather than *the* way to clean the gas and undoubtedly they were right in this course for the plants installed early, even though not the last word of perfection in the subject, will have paid for themselves in bettered operating conditions before the much-to-be-desired best method is developed. It is possible, therefore, with this rapid development in progress, to give only an outline of the subject and to state briefly the principles which underly its application. To do this has been the attempt of the present article.

## Treating Sulphurous Fumes at the Mammoth Smelter

BY AL H. MARTIN

The smelter and baghouse of the Mammoth Copper Mining Company are located at Kennett, Cal., a station on the Southern Pacific Railroad. Control of sulphurous fumes has been a vital problem practically since the commencement of operations, owing to the unfriendly attitude of the neighboring farmers and their complaints of alleged damage by smelter smoke. The baghouse system has been in successful operation about five years, and recent improvements have materially increased its efficiency. The baghouse system was first employed by the Mammoth Copper Mining Company, as relating to copper smelting, although its merit had previously been demonstrated at several lead-smelting plants, and has proved superior to the many contrivances tried in the Shasta field by other operators. Its efficiency is proved by the fact that the Mammoth is now the only smelter operating, while less than eight years ago three other plants also were in action.

The ores of the Mammoth mine are sulphides in the form of massive pyrites, with a large percentage of chalcopyrite. The average copper content ranges from 3 to 5 per cent, together with 4 to 5 per cent zinc and \$1.50 to \$2 in gold and silver per ton. The zinc is a valuable aid in neutralizing the sulphurous properties of the fumes, and gives no trouble in smelting. The blast furnaces are five in number, with three generally in operation. Each furnace has a tuyere dimension of 50 in. by 180 in. and has a capacity slightly in excess of 400 tons of charge per twenty-four hours. About three-fourths of this is ore, the balance consisting of silicious gold-bearing ore, lime and coke.

The fumes from the furnace hoods are led through steel goosenecks into two hopper-bottom brick flues. Each flue is 260 ft. long, and during the passage of the smoke large quantities of the dust settling from the heated fumes drop through the hopper bottoms into a brick-and-steel collecting chamber. From this chamber the fumes are passed into a compartment by means of four round steel pipes at the base of the former smokestack. These pipes are 100 ft. long and 8 ft. in diameter. The second chamber terminates in a flue 15 ft. square and 120 feet long. This guides the fumes into fan chamber which is of balloon-like shape, where the smoke is agitated and cooled by two Sirocco fans 11.5 ft. in diameter. Each fan performs 300 r.p.m. and is driven by a 400-hp electric motor. The fans not only cool the fumes but also serve to draw them from the furnaces and drive them into the baghouse proper.

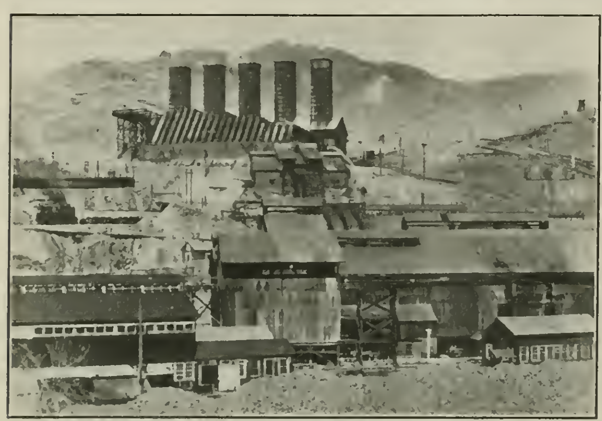
### Improved Arrangement of Cooling Pipes

From the fan chamber the fumes pass into the cooling pipes. There are fifty cooling pipes, arranged five to a section, each pipe having a length of 190 ft. with a 4-ft. diameter. The pipes are so arranged that the fumes pass for two-thirds of their length on a horizontal line, then emerge through a down-sloping section comprising a length of about 60 ft. Formerly the pipes were arranged in three sections. The fumes first passed through a sloping section, thence horizontally, and finally through the down-slanting portion. Tests proved better results were secured by driving the hot gases for a horizontal distance comprising two-thirds of the total length of each pipe. The complete system of cooling pipes embraces an area of 135,000 sq. ft., and the pipes have an aggregate length of 9500 ft.

The principal function of the cooling pipes is the reduction of temperature of the fumes to a point where they will not injure the woolen bags in the baghouse. The fumes have a temperature of 280 deg. C. at the fans, and this is reduced to 130 deg. at the discharge ends of the pipes, showing a loss of 150 deg. in the pipes. The fumes speed through the pipes at an approximate rate of 2700 ft. per minute and discharge into a distributing chamber. The fumes are still too hot for transmission to the bags and their temperature is reduced to 99.3 deg. by admitting cold air through the top of the chamber by means of twelve 24-in. pipes. A special fan supplies the cold air which serves to dilute the gases besides cooling them to the desired point. From this chamber the fumes pass into the baghouse through five short pipes.

The baghouse is 220 ft. long and divided into five bays, with four divisions to a bay. Each division contains 148 bags, or a total of 2960 for the complete plant. Each bag is woven of pure wool and is 34 ft. long with a diameter of 18 in. They are set 21 in. apart, center to center, and each five rows of bags is supplied with a hopper. The lower ends are secured to the floor and the upper edge suspended from vertical racks. The fumes enter the bags through their lower ends and filter through the woolen mesh, to finally escape through the five towers leading from the baghouse into the outer air. The wool catches the solids carried by the smoke and the bags are frequently given a vertical agitation to shake the settled dust into the hoppers lying below. A special shaking device invented by J. E. Egleston is used, the apparatus being operated by electric motors. A wooden trough partly filled with water lies at the bottom of each hopper and the collected solids are drawn off into tanks and settled.

The baghouse is closed with the exception of openings along the sides of the floor and roof, and there is no way for the fumes to escape save through the five towers provided for that purpose. The openings along the floor and roof permit the free entry of large quantities of air to dilute the sulphurous acid gas ($SO_2$). The zinc sulphide is converted into zinc oxide in the blast furnace, and as zinc oxide has a natural affinity for sulphuric acid gas ($SO_3$), this noxious fume is thus neutralized. But to make doubly sure hydrated lime is introduced at the fans at the rate of 30 lb. per hour, effectively neutralizing any vestige of the fume that might resist the action of the zinc.



MAMMOTH SMELTER SHOWING BAGHOUSE AND COOLING PIPES

### Pilot Bag Indicates Efficiency of Neutralization

That a constant test may be maintained to guard against any possible escape of sulphuric acid gas, the company operates a miniature woolen bag, about 2 ft. in length, in the distributing chamber. Should any acid escape, the bag would immediately be destroyed, and as long as the woolen fabric shows no sign of injury it is evident no acid is escaping. This test is maintained for the company's protection and forms a constant register of the efficiency of the practice, in case hostile agencies should claim to have detected traces of $SO_3$ in samples of the exterior air. Under normal conditions the volume of gas passing the fans is 333,000 cu. ft. per minute, and 100,000 cu. ft. of cold air is introduced per minute to reduce the temperature of the fumes. In hot weather it is necessary to use greater quantities of cold air, and the volume frequently reaches 125,000 cu. ft. per minute.

Tests of the smoke leaving the baghouse show that not a trace of dust or $SO_3$ escapes, and the volume of SO is reduced 0.4 to 0.6 per cent, by volume, although the law permits the escape of the gas up to 0.75 per cent by volume. The dust precipitated in the cooling pipes, hoppers and flues contains considerable lead, zinc, silver, gold and other metals, but is of little use to the company as a satisfactory method of treatment has not been devised, despite numerous and extended experiments. A small amount is briquetted and returned to the furnaces, but the greater portion is stored pending the perfection of an economical process for recovery of the metals. Fully 16,000 tons of the whitish-looking dust is stored near the plant, and this amount is increased daily. It is estimated that the metals thus lost would pay for the operating costs of the baghouse system could they be recovered on an economical basis. G. W. Metcalfe is manager of the Mammoth Copper Mining Company, and J. H. Kervin superintendent of the smelter.

## Chemicals Produced by the Aid of Electricity

According to the thirteenth census of the United States, in 1909 there were 34 establishments making chemical and metallurgical products by the aid of electricity, distributed as follows: Illinois, Maine, Maryland, Minnesota, Virginia and West Virginia, each, 1; New Jersey, 2; Pennsylvania, 3; Michigan, 5; New York, 18. Of the total value of products, New York reported $13,401,878, or 72.6 per cent; Michigan, $1,513,198, or 8.2 per cent; Pennsylvania, $903,196, or 4.9 per cent; and all other states $2,633,189, or 14.3 per cent.

The accompanying table shows the products and their value. The class "metals and alloys" includes aluminium, silicon, ferrovanadium, ferrosilicon, ferrotitanium, cuprovanadium, and other metals and alloys. Elements and compounds, produced by the aid of electricity specifically reported and included under the heading of "all other," are phosphorus, sodium, lead oxides, liquid chlorine, carbon disulphide, sodium carbonate potash and potassium bromide.

| | Number of establishments reporting | Quantity, tons, | Value |
|---|---|---|---|
| Calcium carbide | 4 | 60,973 | $2,984,001 |
| Caustic soda | 5 | 19,428 | 1,032,647 |
| Chlorates | 5 | 5,785 | 904,550 |
| Hypochlorites | 5 | 45,976 | 1,506,831 |
| Metals and alloys | 9 | ..... | 7,653,984 |
| Abrasives and electrodes | 4 | ..... | 1,415,799 |
| All other | 11 | ..... | 2,953,649 |
| Total | 34 | | $18,451,461 |

The most important class of products produced by the aid of electricity shown in the table as measured by value, is that comprising metals and alloys, which contributed 41.5 per cent of the total value in 1909.

**An Acid-Proof Lining for Ore Vats.**—In treating low-grade copper ore, one of the methods frequently employed is to dump it into large concrete basins and apply a 10 or 12 per cent solution of sulphuric acid. However, the difficulty encountered in this method is to get basins which will stand the effect of the acid. The usual procedure is to swab the interiors of the basins with an asphaltic mixture. The objection to this treatment is that the asphaltic coating is quickly destroyed by abrasion and has to be renewed at frequent intervals. Tests conducted recently in connection with the use of J-M acid-proof mastic, manufactured by the H. W. Johns-Manville Co., New York, for lining the acid basins, demonstrate that it is entirely successful in overcoming the difficulties heretofore encountered. Acid-proof mastic when laid 1½ in. thick, forms a tough, impervious coating which is unaffected by acid and successfully resists abrasion. The basis of this material is a pure natural asphalt which will give years of service in ore vats.

**The American Mining Congress** will hold its next meeting at Phoenix, Ariz., December 7 to 11, 1914. Methods of safety and efficiency in mining will be considered, and federal aid to the industry.

# Quantitative Blowpiping as an Aid to the Prospector

BY SIEGFRIED FISCHER, JR.

(*Concluded from page 695 of November issue*)

### The Gold and the Silver Assay

In this treatise we will take the gold and silver together. It will be readily seen if only one of these metals is present, to what step the process should be carried.

Weigh out 100 mg (1.5432 grains troy) of the carefully sampled material and place it in the small horn scoop, taking care to brush all of the ore off of the scale pan. Ores containing large amounts of sulphur, arsenic, zinc, or antimony after weighing, need a thorough roasting before making up the charge.

*Roasting.*—Dr. Richards' improved method for roasting is superior to the one given in most of the textbooks, and will be the only one described here. It needs a little more care, but saves greatly in time. On a piece of charcoal a small cavity is made with the charcoal borer. The ore is carefully brushed from the scoop into this hole and spread out along the face of the cavity with the ivory spoon, so that it forms a uniform thin layer. A very weak oxidizing flame is then applied to it, paying particular attention that none of the small particles of ore are blown away.

After a while the material will have caked slightly and then a strong oxidizing flame is applied until no more fumes arise and no odor of $SO_2$ is observed. If this operation has been done carefully the material will have formed a cake which may be readily turned by carefully inserting a knife point at the edge and then turning. The turned side is then strongly roasted and after no fumes and no $SO_2$ odor is observed the sample is ready for the charge, brought back into the scoop and mixed with the necessary ingredients.

The charge will vary according to the ore, and it is difficult to give an absolute rule for making up this charge, but the following will about cover all purposes.

*Borax-Glass.*—The amount used depends upon the fusibility of the ore and upon the amount of materials to be slagged off. One hundred mg will usually suffice. If, however, the ore is hard to fuse due to large amounts of iron, cobalt or tin, more borax-glass must be added during the melting down of the charge.

*Test-Lead.*—As a general rule it is better to use too much test-lead than too little. The amount to be used depends on the amount of other metals present in the ore.

Ores carrying less than 7 per cent Cu or 10 per cent Ni use 5 Zentner (500 mg) test-lead per 100 mg ore. Anything above these amounts will be covered by using 20 Zentner (2000 mg).

Tellurium requires the same amount, i.e., 20 Zentners.

Speiss will use between 10 and 15 Zentners.

Ores containing tin will demand about 7 Zentners.

*Sodium Bicarbonate.*—This flux is mostly used for acid ores, and in small amounts where Cu is present. It forms easily fusible slags, it oxidizes iron and tin, which then pass into the slag, and acts also as a desulphurizer. The amounts to be used depend greatly on the nature of the ore and the function which the soda is supposed to perform. So it is nearly always used with ores carrying sulphur even though they were previously roasted.

A good all-around charge to use in connection with gold and silver ores is the following one:

| | |
|---|---|
| Ore | 100 mg |
| Test-lead | 1500 mg |
| Borax-glass | 100 mg |
| Soda | 50 mg |

The ingredients, after having been weighed out, or measured out, the test-lead in the particular measure, and the borax-glass and the soda in the ivory spoon (one spoonful 100 mg), are brought into the horn scoop with the ore and thoroughly mixed, made up in the soda paper as previously described, and are then ready for the melting down.

*Melting Down.*—Near the end of one of the wide faces of a piece of charcoal bore a hole not too deep. Into this place the charge wrapped in the soda paper so that the bottom is toward the flame of the blowpipe and the side of the little package rests on the side of the cavity farthest from the tip of the blowpipe. Fig. 7 will make this clear.

Now apply a pure but not too strong reducing flame covering the total assay. This will carbonize the paper and melt the charge. When all is melted down, a strong reducing flame is applied. Most of the metals, and some united with sulphur and arsenic, will unite with the lead and melt with it to a button. Earthy materials as well as hard reducible metallic oxides and a small amount of the easily reduced metals melt with the borax to a slag.

To insure a complete collection of the lead, the charcoal should be kept in motion by turning back and forward. The lead should all be in one button and so should the slag. The latter must be in an easily fusible state. If slag is sticky and black, it shows basicity and borax must be added. If stringy and clear, the slag needs more soda. A good lead button should be white. If it is black, it still contains sulphur and must be oxidized. This is done by heating the lead button carefully with the tip of a fairly strong oxidizing flame. Lead oxide will go into the slag but no gold or silver.

This oxidation should continue until the surface of the lead button is light yellow, due to a thin layer of lead oxide. Do not heat too high or spattering will take place, causing a loss of values. When the button has the correct appearance, the charcoal is slightly inclined to insure total collecting of the lead melted, treated with a reducing flame, and the charge poured hot on the anvil. Usually only the lead will pour out, the slag remaining in the cavity. The lead on the anvil is hammered to a cube and is then ready for scorification.

*Scorification.*—This is done on a cupel. Fill the cupel mold with bone-ash, press the stamp down firmly and give the stamp two or three sharp taps with the hammer. On removal of the stamp the cupel should be absolutely smooth. Place the mold in the holder, and grasp the wooden holder between the thumb and the index finger of the left hand, allowing the flat bottom to rest on the bent little finger of the same hand. The cupel is then freed from moisture by heating.

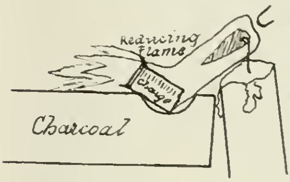


FIG. 7—ARRANGEMENT FOR MELTING DOWN

When dry the small button is placed in the middle of the cupel with a pair of forceps. The cupel is slightly inclined towards the blowpipe, and a reducing flame applied to reduce oxides on the surface of the button until it is melted down. Then the assay is treated with a strong oxidizing flame.

Scorifying should be done quickly. The lead will form litharge which is partly absorbed by the cupel. Much of it, however, stays in the liquid form surrounding the ever-decreasing button. When the surface of the button as seen is about 3 mm in diameter the melt is allowed to cool.

When set the mass is removed from the cupel, placed on the anvil, and the little button freed from litharge and bone-ash by hammering. It is good practice to clean the button by brushing with a glass or stiff-haired brush. The small, clean button is then ready for the fine cupellation.

*Fine Cupellation.*—Use a new, dried cupel. Place the little button on it so that it lies near the left edge. Incline the holder so that the little button cannot roll towards the blowpipe. Heat the button with a nearly vertical oxidizing flame until it melts.

When melted, take flame off the button and heat the bone-ash immediately surrounding it, rotating the holder with the two fingers so that the button will always come in contact with a fresh surface of bone-ash. The button will thus describe the path of a spiral toward the center of the cupel. The litharge will be absorbed by the cupel and, when the last trace of the oxide is removed, the button suddenly brightens. Then the operation is completed. This sudden flaring up is termed "brightening."

If silver alone is present this is the final operation and it only remains to weigh or measure the button. If the button is a large one it may be weighed, if small measured on the Plattner scale. *A large button may be flattened on the anvil, cut in half, each half put on cupel with test-lead brought down to new buttons and then measured on scale and weights combined.* The operation of measuring on the Plattner scale has already been described.

If the button is an alloy of silver and gold, then another operation is required, namely, parting.

*Parting.*—Under this term is understood the separation of the gold and silver. This is usually done by treating the button with nitric acid. The button is placed in a small porcelain dish. A drop of concentrated nitric acid is added to it and one or two drops of water. Holding the dish between thumb and index finger of the right hand, it is slightly inclined so as to have the button and acid in one place, and then gently heated over a flame. As the button is attacked, an evolution of heat will take place.

One cannot be careful enough here, because if spattering becomes very strong the small particles of gold will fly out of the dish. When the activity ceases, water is added. This is then carefully decanted, or, according to Dr. Richards, a small piece of filter-paper is so folded that it forms a fairly sharp angle. With the tip of this the solution is absorbed.

Wash again and repeat the treatment with strong nitric, washing finally twice.

This leaves the gold in a brown spongy mass. If the reaction was not too lively, all will be together. At times, however, the gold will be in several particles and these must be all collected. To gather the gold it is best to cut a small piece of test-lead from the solid piece, put it on the point of the forceps with the clean surface down, and then press this surface hard against the small gold particles. They will stay on this surface without difficulty and may be thus collected. This test-lead holding the gold is then cupelled to a button.

There is one thing which must be remembered, and that is, that not all alloys of gold with silver will be attacked by nitric acid. The button must have more than 50 per cent of silver. At the mint one-third gold to two-thirds silver is customary. If the button by its color shows that the gold predominates, then silver foil is added to make the ratio correct. The button, after having been weighed or measured to ascertain its total weight, is wrapped in the required amount of silver foil, folded into a small piece of test-lead and cupelled down to a button and then parted as before.

The final gold button is weighed or measured. If the alloy was weighed, the difference between it and the weight of gold will give the weight of silver.

If it has been measured it will only give the volume and not the weight. All measurements on the ivory scale give the volume and the figures giving percentage or weight have been calculated from the volumes. As I am going to describe the use of Dr. Richards' scale it will be unnecessary to describe the procedure on the ivory scale as it is similar to Dr. Richards'.

In connection with this I would like to mention the use of Dr. Richards' scale. The button of the gold and silver alloy is dropped into the groove several times and the diameter noted. The mean of the maximum readings is used as the correct one. In the table that accompanies the instrument the weight of silver is found, if the button is all silver. Dividing this weight by the specific gravity of silver, 10.073, we obtain the volume of the alloy.

After the parting the gold button is also measured in the same way. Its weight is divided by the specific gravity of gold, giving the volume of the gold button. Both these volumes are in mm³.

Subtracting the volume of gold from the volume of alloy gives the volume of silver.

Multiplying the corresponding volumes by the specific gravity of gold and silver will give the corresponding weights of the two metals, from which the ounces or percentages can readily be calculated.

$$\text{Scheme: Alloy } \frac{\text{mg silver}}{\text{spec. grav. silver}} = \text{volume of alloy in mm}^3$$

$$\text{gold } \frac{\text{mg gold}}{\text{spec grav. gold}} = \text{volume of gold in mm}^3$$

Vol of alloy — vol. of gold = vol. of silver in mm³.

Vol. of silver × spec. gravity of silver = weight of silver in mg.

Vol. of gold × spec. grav. of gold = weight of gold in mg.

For convertion of mg into ounces see description of Plattner's scale.

*Precautions in gold and Silver Assay.*—If tellurium is not all eliminated it goes into the lead button and in final cupellation shows deleterious effects. It lowers the surface tension of the lead, causes it to spread out, forming separate globules, each of which contains some of the values. These small buttons cannot be collected. So it is essential to obviate this effect by adding enough test-lead to the initial charge.

It is essential that the little silver or alloy button be cooled slowly to prevent sprouting, due to the absorption of oxygen while hot which is liberated again immediately before cooling, causing a loss by spattering.

If during cupellation some bone-ash becomes loose it at times happens to collect on the button. When this occurs, take a little piece of test-lead, place it on the button and melt. It will melt together with the button, increasing the mass of same, and by inclining the cupel the button will liberate itself from the bone-ash.

If much copper is present in the assay one cupellation is not sufficient. More test-lead must be added to the button during the process and cupellation repeated until the button is free from all copper. If copper is still present after first fine cupellation the button will have a flattened appearance, and at times shows black spots of copper oxide.

The heating is another important factor in the fine cupellation. If the button is heated too high, silver will volatilize. If not high enough the litharge around the button solidifies and sticks to cupel. If this occurs, increase the intensity of the flame. The heating should be such that the litharge is absorbed rapidly by the cupel.

Removing the button from the cupel requires some care. To prevent the losing of the button it is always advisable to work over a sheet of paper with edges turned up, thus forming a tray. When the button has cooled on the cupel it may be carefully pried loose from the same with the blade of a penknife, and then lifted out with the forceps, being sure that there is no pressure exerted which might change the shape of the small, nearly spherical granule. The button may also be removed from the cupel with the button pliers. One should remember always to handle it so that its form is retained. The button is then thoroughly cleaned from bone-ash by rubbing it gently with the tip of the finger on a piece of filter-paper, or with a brush.

### The Copper Assay

In this operation it is desired to retain the copper in the melting-down process. If the ore contains sulphur, arsenic, antimony or zinc it must be roasted, after weighing out the sample. One hundred mg of the ore is used for the assay. This is mixed with 5 Zentners of test-lead and enough borax to make an easily fusible slag. Mix the ingredients of the charge and make up in the soda paper. Melt down on charcoal as previously described.

The slag should have a black appearance and show no red coloration. If red shows in slag, copper has been oxidized and must be reduced back to metallic copper by rolling the button around in the slag under the action of the reducing flame. Another method is to add a small piece of test-lead to the assay. This lead on melting, together with the button, will take up the reduced copper, and the process can continue.

If the borax sticks to the charcoal increase the heat of the reducing flame. When the charge is thoroughly melted down and all the metal collected it is poured on the anvil and hammered to a button.

Make a new hole in the charcoal and place button into it with crystallized boric acid. As this fuses harder than borax, a hotter flame is required. Melt first with reducing flame, and then oxidize. The lead forms an easily fusible lead borate of a greenish color. If there is any red indication it shows loss of copper.

To get copper out of slag, if any was lost in this manner, apply the reducing flame while rotating the button in the slag until the red coloration has disappeared. Loss in copper can be readily observed by the slag showing a sealing-wax red color in the light of the luminous flame.

The slag must always be kept fluid, and as long as this is done one may rest assured that the button is in a liquid form. When the slag commences to bubble, it shows that the maximum amount of borate possible has been formed. Any more heating will not aid the operation, but the charcoal will reduce some of the lead in the slag back to metallic lead.

When bubbling starts allow button to solidify, and while slag is still pasty remove the button with the forceps and immerse it in water, which is kept close in one of the small porcelain dishes. This immersion in water cleanses the button from adhering slag. Dry on filter-paper, place the button on a new place on the charcoal with fresh boric acid and oxidize carefully. Repeat this as often as required.

When the lead content gradually decreases, the button becomes harder and harder to fuse. The lead color disappears and the copper color takes its place. The melted button will assume a nile-green coloration when copper is reached. On cooling the metal left will have a salmon color if pure.

If the button is finished it should be malleable, and when flattened out on the anvil it should show no cracks along the edges. If edges show cracks the button must be treated again with boric acid and newly tested. After assuring oneself of the purity of the metal button it is weighed, and if the ore contains only the copper as values the operation is completed.

If gold and silver were also present in the ore, they will be contained in the copper button. After weighing this it is brought onto a cupel with test-lead and fine cupelled. This button will then contain the gold and silver, and is weighed or measured. Its gold content is then determined by parting, and the results interpreted as described under the heading of gold and silver.

With a little practice and care no hole need be bored in the charcoal for treatment with the boric acid. Simply place some crystals of boric acid on a flat surface of the charcoal and melt it down. Then place the button on the melted acid and treat it as above described. This method saves time and one has a better opportunity to observe what is taking place.

### Cobalt and Nickel Assay

These metals as well as iron must be bound to arsenic to enable their qualitative determination. If copper is also present, it may be obtained as arsenide also. As a rule, ores carrying nickel will also contain cobalt and vice versa. The operation is based on the principle that when these metals occur together they may be successively oxidized out in the presence of borax, iron going first, then cobalt, nickel and copper.

Nickel, iron, cobalt ores not in the arsenide form must first be arsenicised. This is done by mixing 100 mg of the ore with 100 mg of powdered arsenic, wrapping the mixture in a soda paper, and placing the tightly and well-packed capsule in a test tube, heating this carefully in the non-luminous flame (alcohol lamp) at first, then increasing the temperature until the tube is red hot. The tube should be turned about its axis to prevent the charge in the soda paper from adhering to the glass. An arsenic mirror will form on the sides of the test tube, and when this does not seem to increase any more, the operation is completed. The charred paper containing the now arsenicized charge is then emptied onto the horn scoop ready for mixing with the other ingredients.

The method of procedure is as follows: Weigh out 100 mg of the ores, if needed arsenicise, if not mix directly with 50 mg of borax and 15 mg of soda, otherwise after arsenicising; wrap in soda paper, and reduce on charcoal until melted down, and metal collected in one button.

Now use oxidizing flame, and remove, first, the iron by continued oxidation in presence of fused borax. As long as iron is present the slag will show a distinct green coloration, and on allowing the button to cool it will show a black surface due to an oxidation product of iron and arsenic, probably a basic compound. If much iron is present the treatment with fused borax must be repeated, similar to the treatment of copper with boric acid. When nearly all the iron is gone the little globule of metal on cooling will be covered with iron oxide.

At last the metal button will show a metallic appearance. It is then removed, and after freeing it from the adhering slag, the button is placed on the charcoal without borax and treated with the reducing flame until no more arsenic is given off. The button is then free from iron and is weighed. One hundred mg-weight of button will give the amount of $Fe_2As_2$.

The residual button is again treated with borax in the oxidizing flame. The slag now will show the cobalt-blue coloration. The button on cooling shows a pinkish iridescence. If much cobalt is present the treatment with borax must be repeated by removing the button each time, immersing in water and rubbing clean of slag, and then placing on charcoal with fresh borax.

As the operation nears completion and the cobalt is nearly all eliminated, the pinkish color of the button disappears, the button is harder to keep melted.

When, on pinching some of the pasty slag between the platinum forceps and raising it slowly, it shows a purple color, and the button on cooling shows an apple-green tinge after all the cobalt is out. The button is cleaned and weighed. Then (100 mg — $Fe\ As_2$) — weight of button will give amount of $Ni_2As$.

If last weight is all Ni then the operation is completed, the weight of the button being then $Ni_2As$. But if the nickel left also contains copper, gold and silver then it is best to proceed as follows: Melt the button with about an equal amount of test-lead, and treat it with boric acid as in copper. The nickel is oxidized simultaneously with the lead with little or no loss. When the button shows the characteristics of a copper assay, it is weighed giving the weight of copper, gold, and silver. From here on the operation is similar to the assay of copper, gold, and silver alloys.

*Precautions.*—In heating always aim to have the slag in a melted condition, by melting button and then keeping the flame in the immediate neighborhood of it on the slag. It is far better for the novice to make a small cavity in the charcoal and to melt down in it, as it needs considerable skill to do the oxidizing on the surface of the coal directly. The button has a tendency to roll along the edge of the slag and unless carefully watched will roll off if not in a cavity.

The compounds formed and weighed are the following:

$Fe_3AS_2$ .................. 52.8% Fe
$Co_2AS$ ..................... 61.1% Co
$Ni_2As$ ..................... 61% Ni
$(Cu + Ag + Au) — (Ag + Au) = Cu$
$(Ag + Au) — Au = Ag$
= % Ag
100 mg — Weight of Co, Ni, etc., button $Fe_3As_2 \times 0.528$ = % Fe.
A mg — " " Ni, etc., " $Co_2As \times 0.611$ = % Co
B mg — " " (Cu + Ag + Au)
button $Ni_2As \times 0.610$ = % Ni
(Cu + Ag + Au) — Ag + Au = % Cu
(Ag + Au) — Au = % Ag

The example used is the most complicated one, including six metals.

If there was no iron present the first button obtained would be metallic in appearance and the slag would in all probability show slight losses of the metal present. A blue tinge would show cobalt and a smoky-brown tinge would show nickel. Great care should be exerted by the first melting down, to use a pure reducing flame so as to diminish possible loss. The color of the button is also a reliable source for judging what metal is on hand, pink indicating cobalt, white nickel.

### Mercury Assay

The assay of mercury is very simple. 0.5 gm of the ore is weighed out, mixed with 1 gm of litharge and carefully brush into a glass tube about 19 cm long and 6 mm diam. This glass tube must be closed at one end and bent, as shown in Fig. 8C.

The glass tube is best prepared as follows: Take a glass tube about double the length required. Heat at the middle and draw out. The drawn ends will have a pointed appearance (Fig. 8A) and must be further heated and rounded off as Fig. 8B shows. One of the straight closed tubes is now bent about 2 3 back from the open end, by heating the desired place in a luminous flame while rotating the tube slowly. After a while the glass softens and the tube is readily bent to the desired angle. To prevent cracking it is well to keep the heated portion covered with the soot of the flame until cold.

Before putting the charge in the tube it must be heated so as to drive out the moisture, and prevent the charge from sticking in the straight part of the glass tube. The charge is best put into the tube by folding a card or slip of paper lengthwise, putting the sample on it and shaking it carefully into the tube. Do not forget to brush the card free from any adhering particles. If some of the charge should stick to the tube a small camel's hair brush will serve to remove the particles. The actual charge is then followed by a good layer of litharge.

When the tube is ready for heating, the straight part of it should be absolutely clean. A loosely rolled piece of filter-paper placed on the mouth of the tube will take up any moisture from the charge. The closed end of the tube is then carefully heated. Slowly at first, because there may be moisture in the charge which on rapid heating would blow the litharge out of the bent into the straight part of the glass tube and spoil the assay. When all the moisture is out, the sample is heated until the charge is melted. The mercury will have sublimed and collected in metallic form in the straight part of the tube.

Allow to cool and take care to hold the straight part horizontally so that no mercury is lost. Cut the tube with a file just at the bend, place on anvil and break off the part containing the charge. It is well at this stage to place a small porcelain dish under the open end of the tube, so as to collect any mercury, if it should roll out. When the bent end has been carefully removed, tilt the glass tube over the porcelain dish and with a camel's hair brush attached to a stick or piece of glass rod, brush the mercury into same. Before removing the brush, tap it sharply several times so as to cause any mercury sticking to it to fall into the dish. The globule of mercury should be clean and free from any litharge. It is then weighed, and gives the amount of mercury in the ore.

Filter Paper
Litharge
Ore + Litharge.

FIG. 8—ASSAY OF MERCURY

It is best to weigh the mercury wrapped in a weighed piece of paper to prevent it from amalgamating with the metal of the scale pan. This method may be used for all sulphide ores containing mercury, with one exception, namely, idrialite, a mixture of cinnabar, clay, gypsum, pyrites and bituminous matter which gives off volatile matter contaminating the mercury.

For chlorides the same charge is used with an addition of soda, the amount of this ingredient being three times that of the ore. The method of procedure is then the same.

### Conclusion

There are further quantitative determinations possible, such as tin and lead, but these lack the certainty that those mentioned possess, and for this reason I will simply refer the reader to the book offering the best information on this kind of work: Plattner's Manual of Qualitative and Quantitative Analysis with the

Blowpipe, translated by Henry B. Cornwall and published by D. Van Nostrand Co., New York City.

It is of interest to know that by the aid of the blowpipe moisture determinations may be made as well as approximate coal analysis. These are, however, of less use to the prospector. To the jeweler quantitative blowpiping may be of use in determining the composition of alloys. But the main use of quantitative blowpipe work lies in the field of prospecting, as it is a quick and simple means of obtaining results, saving both money and time.

Finally I will cite a few examples showing the accuracy of the different methods. These results have been obtained by different individuals on the same ores.

The inaccuracies here are not so much due to the method as to the lack of experience of the student, although in the determination of the iron there will always be more or less variation due to possible chances of losses in the operation.

The most accurate results are obtained with the gold, silver and copper assays. For the others, especially iron, cobalt and nickel much more practice is required. Considering the amount of work the average prospector has done by the assayer to obtain information as to the possible value of his ores, one can readily observe that the time spent in acquiring these methods of procedure will soon pay, as the results are certainly close enough to give him positive information on the practical value of his ore—and that is what he is after.

**The Ohio Copper Company** is in the hands of receivers as a result of voluntary and involuntary petetions in bankruptcy. The mine and mill near Salt Lake City are closed. Mr. F. Augustus Heinze, one of the principal holders of stock and bonds of the company, has protested against the proceedings on the part of the management, and has asked that the bankruptcy adjudication be vacated.

**The first unit** of the new mill of the Alaska Gold Mines Co., near Juneau, Alaska, is expected to be in operation in December, according to a statement attributed to D. C. Jackling, who has recently returned from a trip to the property. The rated capacity of the mill is 6000 tons per day, but it is stated that alterations in the original plans will make it possible to exceed this by one-third or more. It is expected that the entire plant will be in operation by the middle of 1915.

# An Electrical Process for Detarring Gas*

BY F. W. STEERE

The object of this paper is to give a brief outline of the development of a commercial process for the precipitation of suspended particles from gas by high-tension alternating current, and the practical application of this process to the removal of tar from coal gas and from producer gas.

As the early experiments with high-tension discharges for precipitating suspended matter from gases have been reviewed quite thoroughly in recent articles by Prof. W. W. Strong, Dr. Cottrell, and others, only a brief mention of them will be made here. The phenomenon seems to have been first discovered as early as 1825, but very little, if any, effort was made to make practical use of it. From the first the precipitation of smoke seems for the most part to have claimed the attention of experimenters. The possibilities of separating gold, silver, and other metals carried in smelter fumes in a finely divided state, and the precipitation of acid fumes from smelters have also been fertile fields for inventors for years, the first patents having been issued as early as 1886.

The question is naturally asked why this method of purifying gases has not long since been in commercial use. Possibly the answer is found in the fact that although the phenomenon may be readly demonstrated on a laboratory scale with very simple apparatus, many serious difficulties were encountered in the various attempts to develop commercial apparatus embodying the same principles, but capable of continuous operation with little attention. A beautiful demonstration may be given with a hand-operated static discharging in a glass cylinder, or, on a larger scale, with an X-ray outfit discharging from wires suspended in ordinary piping, etc.

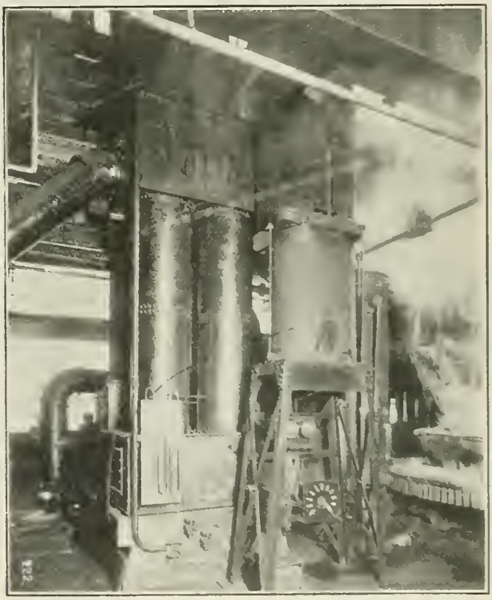

FIG. 1—ELECTRIC DETARRING APPARATUS FOR COKE OVEN GAS AT THE DETROIT PLANT OF THE SEMET SOLVAY CO.

---

*A paper read before the American Gas Institute (New York meeting, October, 1914). Copyright, 1914, by American Gas Institute. Subject to Author's Corrections.

Such work, however, is hardly the first step towards the solution of the problem of a complete installation doing service and earning dividends 365 days in the year under the conditions found, for instance, in the ordinary gas plant.

The process recently developed by Dr. Cottrell shows what can be accomplished in precipitating dust. The Cottrell process consists in rectifying high-tension alternating current on rotating switches driven by synchronous motors, giving an intermittent unidirectional discharge. A plant using this process has recently been completed for precipitating the dust from the cement works of the Riverside Portland Cement Company, Crestmore, Cal., and acording to recent reports is giving excellent results.

Herbert A. Humphrey seems to have been the first to use high-tension electric discharges to precipitate tar. Prior to 1897 we learn that Mr. Humphrey was using a static discharge within a small glass vessel through which he passed a known volume of gas, for making quantitative determinations of the tarry matter carried by the gas.

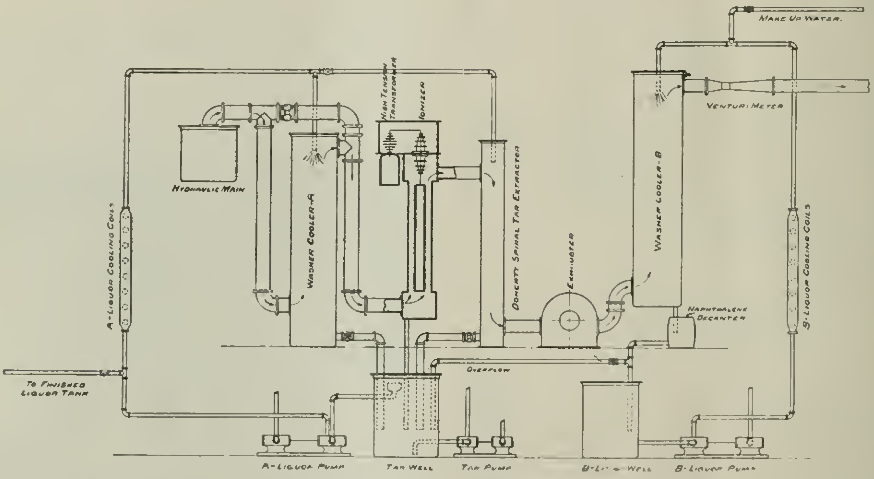

FIG. 2—DIAGRAMMATIC SKETCH OF THE EXPERIMENTAL PLANT FOR THE ELECTRICAL DETARRING OF COKE OVEN GAS AT THE DETROIT PLANT OF THE SEMET SOLVAY CO.

In 1911 work was started along these lines in the research laboratories of the University of Michigan at the suggestion of Prof. A. F. White. This work consisted for the most part in repeating the experiments of the early investigators and in attempting to apply the Cottrell process to the precipitation of tar from coal gas. The results of these preliminary investigations were given to the gas fraternity in a paper entitled "The Electrical Separation of Tar from Coal Gas," by A. F. White, J. W. Hacker, F. W. Steere, which appears in the *Proceedings* of the Michigan Gas Association for 1912.

The author, while engaged in this research work at the University of Michigan, became convinced that with a suitable arrangement of electrodes and apparatus, alternating current might be used instead of rectified current. The complications and difficulties of rectifying alternating current of from 40,000 volts to 80,000 volts on synchronous-motor-driven rotating switches will be readily appreciated. No gas man would relish the idea of having such an outfit as a part of his plant equipment to be looked after by the average operator, especially in those states having workmen's compensation laws.

By the use of alternating current the synchronous motors and rotating switches would be eliminated as well as the leads carrying the high-tension current from the transformer to the rectifier and from the rectifier to the electrode connections. Further, with the simple use of alternating current the transformer may be mounted on the ionizer, one terminal may be grounded and the other connected directly to the electrode terminal. With the terminals and connections completely inclosed so that no high-tension parts would be exposed, and with no moving parts requiring attention or inspection, the element of danger would be absolutely eliminated.

An opportunity was provided at the Detroit plant of the Semet-Solvay Company to work out these ideas and develop the theory on which this work is based. This theory, although far from complete, has proven sufficiently accurate to guide us in perfecting a detarring process which is in commercial use to-day.

In attempting to briefly outline the electrical action, we must keep in mind, first, that the gas molecules themselves possess both positive and negative electrical constituents which can be separated by X-rays, beta and gamma rays of radium, brush discharge from points, corona discharge from wires raised to high potential, ultra-violet light, etc. This process of separating neutral gas molecules into electrically charged parts or ions is called "ionization." It is outside the scope of this paper to attempt to discuss the ionic theory, but it should be noted that ions as such are very unstable and cease to exist, that is, recombine to form neutral molecules, almost the instant they are outside the ionizing influence. A very few molecules are continually splitting up, presumably because of the trace of radio-active substances found in most gases as well as in the atmosphere.

Professor Millikan, of the University of Chicago, has studied the movements of a small drop of oil between two oppositely charged condenser plates when attacked by atmospheric ions.* The drop received a charge when atomized, so by throwing on and off the electrical field, the drop is made to beat up and down between the plates. The instant an ion attaches itself to the drop the fact is made known to the observer by its change in speed, this change depending on the sign of the ion and the charge on the drop. The important and interesting thing to note is that with over a thousand drops studied in this way, the change of speed was always exactly proportional to the number of ions attached to the drop.

---

* "The Oil Drop Method of Studying Electrical Phenomena in Gases," R. A. Millikan, *Trans.* American Electrochemical Society, Vol. XXI, 1912.

Let us recall that there were about twenty-seven billion molecules in 1 c c of ordinary air and that each molecule may be separated into at least two ions. When just one of the possible fifty-four billions ions per cubic centimeter attached itself to the oil drop it instantly caused an appreciable change in its velocity. Imagine then the violence with which this drop would have been thrown about if all the molecules surrounding it had been ionized.

This is just the condition we bring about in the electrical detarrer. The gas carrying the minute tar globules is swept into an intense ionizing field. Billions of gas molecules on every side are being torn apart. The resulting ions rush madly about in their effort to recombine. The unsuspecting tar globules find themselves in a storm center of unseen forces hurling them in every direction. The time occupied in the passage of the tar particles through the electric field is brief and it might naturally be supposed, as it herefore has been, that an aimless to-and-fro movement of them would be the result of the applied energy. It would be hard to conceive of a condition more favorable to impact between tar particles, and experience shows that either because of this impact, or for some reason as yet unknown, agglomeration results and the dense tar mist is almost entirely dissipated leaving a relatively few large tar drops in its place.

This rather figurative description will seem more real to those who have witnessed this remarkable phenomenon within a glass vessel filled with dense fumes or fog. The instant the current is turned on, the whole field can be seen to clarify. The commercial importance of this becomes more apparent when we realize that this action can be brought about at almost any desired temperature.

No attempt is made to free the gas of these agglomerated tar particles while it is still in the ionizing field. The apparatus is so arranged that everything is swept on through into some form of mechanical extractor where a complete removal is effected with very little power loss. The Doherty centrifugal tar extractor worked very well to accomplish this; the old type P and A machine also became a very efficient tar extractor when placed after the ionizer.

The whole process may be summed up in this: It is practically impossible to free the gas from tar in the extremely fine state of subdivision which naturally results from rapid condensation. There is no difficulty in removing relatively large drops, and the electrical treatment simply converts the fine mist into the large drops.

A diagrammatic sketch of the experimental plant built at the Detroit Coke Ovens is shown in Fig. 2. The plant was not built complete as shown here at first, but was added to and altered as the work progressed. The course of the gas may be readily seen by referring to the cut. From the hydrauic main the gas passes either to a small washer-cooler *A* or by-passed this directly to the ionizer, depending on the temperature desired for the test. After the ionizer came the mechanical extractor, of which various types were tried. This apparatus was all on the suction side of the motor-driven exhauster Following the exhauster was a second washer-cooler *B*, where the final cooling was effected. Measurements of the gas volume were made with a Venturi meter. The capacity of the plant was about 30,000 cu. ft. of gas per hour.

All work was done on the rich gas, that is, the gas given off during the first six or eight hours of the coking period. To insure complete recovery of ammonia and in other respects to duplicate as far as possible the condensing system used at the Detroit coke oven plant, two sets of cooling coils were used, one for cooling the circulating liquor from washer-cooler *A* and from the mechanical extractor when liquor was circulated through it, and one set for the circulating liquor from washer-cooler *B*. The make-up water was added to the *B* system and overflowed to the *A* system. When the *A* liquor was up to strength, it was pumped to the weak liquor storage tank.

Extensive use was made of the filter paper method of studying the condensed matter carried by the gas. This consists of aspiring a known quantity of gas through two thicknesses of filter paper, the resulting stain indicating relatively the quantity and to some extent the quality of the suspended matter. With the ordinary methods of condensing and cleaning, quantitative determinations by this method are unreliable, especially with producer gas, as an appreciable quantity of the very fine tar mist will pass readily through two thicknesses of filter paper. When the gas carries large quantities of tar mist, the aspirator bottle will be full of the dense brown fog which has passed through the papers. Over 1200 of these tests were taken in the course of this work and, although practically white papers were taken, we believe we have more reliable and conclusive evidence of the completeness of the detarring, which will be mentioned later.

The best results were obtained with the gas entering the ionizer at a temperature of from 65 deg. to 80 deg. C. (149 deg. to 176 deg. Fahr.). There was every indication, however, that with a gas not saturated with water vapor, the electrical action would be fully as effective at very much higher temperatures. Since this action is purely electro-mechanical in so far as it affects the tar,

FIG. 3—LARGE GAS ENGINE AT FORD WORKS, OPERATED BY ELECTRICALLY DETARRED PRODUCER GAS

the higher the temperature of ionization the more condensate will come down with the subsequent cooling. If the lower temperature condensate proved troublesome, a second treatment at a lower temperature could be used.

A very interesting development was the effect on the gasman's old enemy, naphthalene. Naphthalene by itself in the gas works, is quite a harmless and possibly valuable by-product. The trouble is all in the company it keeps; when mixed with enough tar to act as a binder, it is exceedingly troublesome, but when the tar is removed before the naphthalene condenses in appreciable quantities, the real cause of the trouble is eliminated.

This segregation was brought about as follows: Washer-cooler *B* was sealed in a barrel through a 3-in. pipe. The circulating liquor was drawn from the bottom of this barrel, cooled in pipe coils and returned to the top of the apparatus. It was found that with the foul gas entering the ionizer at about 70 deg. C. (158 deg. Fahr.) the naphthalene vapor was condensed in washer-cooler *B*, where the gas was cooled, and the crystals were carried out of the apparatus through the 3-in. pipe with the liquor into the seal barrel, and immediately came to the surface. The separation of the crystals and liquor even in this small vessel was almost perfect. After several weeks' run there was not the slightest indication of any deposit in the cooling coils or liquor lines. The gas was cooled in washer-cooler *B* to from 16 deg. C. to 25 deg. C. (60 deg. to 77 deg. Fahr.). Picric acid tests which were run to determine the naphthalene carried by the washed and cooled gas, checked invariably with the tables giving the theoretical naphthalene saturation at the observed temperature.

The whiteness of the naphthalene crystals recovered and the fact that there was absolutely no indication of any deposit in the coils or pipe lines, we consider proof conclusive of the complete freedom from tar.

Although at present naphthalene is a drug on the market it possesses so many of the characteristics of an ideal fuel for certain power purposes we are confident that it will become an important factor when there is a sufficient and dependable supply available. The farm tractor seems to offer an attractive field for investigation along these lines, especially in view of the success with which naphthalene is being used as an internal-combustion engine fuel abroad.

The two most valuable constituents of commercial light oil are benzol and toluol. The absorbing power of tar for these oils increases as the temperature decreases. With the tar as a fine mist the surface of contact between the tar and condensable hydrocarbon vapors is a maximum. It follows theoretically that if the tar mist is agglomerated to larger particles at relatively high temperatures the tendency for these oils to become absorbed by the tar is greatly reduced, and if this is followed immediately by a complete removal of the tar, this absorption of light oil by tar is reduced to a minimum.

Considerable work was done along these lines which undoubtedly establishes this theory within the range of our observations. Unfortunately we were unable to get gas above 80 deg. C. (176 deg. Fahr.), entering the ionizer, but analysis showed that the tar precipitated with the gas entering the ionizer at this temperature, contained but a trace of light oil, while the gas tested simultaneously, showed the highest light oil content. Light oil is, of course, not made by this process, but these experiments have shown beyond a reasonable doubt that the percentage of light oil carried by the gas and hence its illuminating power can be very materially increased. In coke-oven practice this has a distinct commercial importance with the increasing value of benzol as a motor fuel, and of toluol for use in the manufacture of explosives.

Cleaning producer gas for use in gas engines is one of the later developments of this process. Producer gas tar is very much more pitchy than coke-oven tar and the tar mist particles hardened at very much higher temperature. The tar mist carried by this gas when rapidly condensed, as is necessary in a compact plant, was found to be in such an extremely fine state of subdivision that a large per cent of the tar passed readily through two thicknesses of filter paper. It is this extreme fineness and relative hardness of the tar particles which makes the complete cleaning of producer gas by purely mechanical means a physical impossibility without an excessive power loss.

Arrangements were made with the Ford Motor Company, of Detroit, to try this process on the producer gas driving their large gas engines. At the outset many unlooked-for difficulties were encountered which required considerable time and study to overcome. Had it not been for the sportsmanlike attitude shown by Mr. Edward Gray, chief engineer and designer of the engines, in giving us every opportunity to study out these problems, we might have a very different report to make at this time.

The electrical process was eventually put in run at the Ford plant on Jan. 21, 1914, and up to this date has not been out of service one minute while the plant was running. All the difficulties which were in any way way due to tar have been entirely eliminated. The regular operating force start up and stop the process with perfect confidence and at no time has it required any special attention.

In conclusion I wish to again call attention to the fact that this method of attack goes to the source of all the difficulties, that is, the almost molecular fineness of the tar particles which persist in carrying along with the gas in defiance of all mechanical scrubbers and washers. An enormous amount of time and study has been required to bring this process to its present stage, but notwithstanding the various difficulties, we now have in commercial operation a plant which requires no attention, is self-cleaning and is started or stopped at will by the regular operators.

The value of this electrical detarring process to the illuminating gas industry is as yet problematic, but it presents some very interesting possibilities. Its adoption would make possible a somewhat higher illuminating power with a given gas than is obtained from the same gas when the tar is removed in the usual way. By its use followed by a washer-cooler, tar-free naphthalene can be condensed and removed from the gas without causing stoppages in the condensing apparatus. The tar can be completely removed from the gas at any desired point in the gas condensing and scrubbing system; the complete removal of tar, prior to condensing gas, will make a relatively clean weak liquor possible. For the by-product coke-oven industry the process promises to be of value in connection with the direct method for the manufacture of ammonium sulphate, as well as for its possibilities as a means for recovering naphthalene and increasing the yield of benzol and tuluol.

The commercial plant for detarring producer gas which has now been in continuous and successful service at the Ford Motor Company for several months has demonstrated beyond all doubt the value of the process for this branch of the industry. With these possibilities it seems not unlikely that this process may eventually play an important part not only in cleaning producer gas, but also in the manufacture of coal gas.

Detroit, Mich

# Note on the Preparation of Pure Calcium Carbide

BY M. DEKAY THOMPSON
EXPERIMENTS BY L. R. GONZALEZ AND K. B. BLAKE

In the reaction according to which calcium carbide is prepared technically, $CaO + 3 C = CaC_2 + CO$, the carbide is necessarily contaminated by the presence of lime and carbon, and it is not possible to remove these impurities.

A number of methods of making calcium carbide in the pure state have been described, but in attempting to follow directions for the purpose of making pure calcium carbide for experimental purposes, difficulties were encountered which were not mentioned in the papers describing these methods. Our experience with the different methods that looked promising are given below.

### THE ACTION OF PURE CARBON ON METALLIC CALCIUM

The first method tried for producing pure calcium carbide is the action of calcium on finely divided carbon, as described by Moissan[1]. According to Moissan this synthesis takes place at a low temperature and can be produced by heating a mixture of carbon and calcium in a porcelain crucible over an alcohol lamp. The heat evolved fused the carbide.

The calcium used in our experiments was furnished in the form of a rod about two inches in diameter, and was evidently made by the Rathenau[2] process.

Turnings were made from this rod in a lathe, keeping the metal covered with a film of kerosene during the operation. The turnings were kept under petroleum ether. It was analyzed by dissolving a weighed portion in water and titrating with standard hydrochloric acid, using methyl orange as an indicator. Any sodium or magnesium present would be counted as calcium. Magnesium and iron were shown to be absent. The purity found by this method was 98.17 ± 0.01 per cent.

Carbon was prepared in three different ways. (1) Sugar was added to sulfuric acid, causing carbon to separate in a spongy mass. Some sulfuric acid was reduced to sulfur dioxide, which was recognized by the odor. The mass was washed, dried, ground up, and boiled in caustic potash for several hours, and then in successive portions of water until the sulfate was entirely removed. This was then dried and ignited at a dull red temperature for one hour.

(2) Carbon was made by allowing acetylene to burn with a smoky flame and the soot collected on a copper vessel filled with water. Acetylene was generated from commercial calcium carbide and was purified[3] by passing in succession through a concentrated solution of chromic acid in sulfuric acid, a saturated solution of lead nitrate, and finally through a drying tower containing a layer of bleaching powder below a layer of calcium chloride. Ten grams of carbon were prepared by this method, which after igniting had a bluish tinge.

(3) The third method consisted in burning granulated sugar, grinding to powder and washing free from caramel. This was dried and ignited at a dull red temperature for half an hour in a covered porcelain crucible. This product had a shiny black color.

Equivalent quantities of calcium turnings and carbon made from sugar and sulfuric acid (2.156 gr. Ca, 1.275 gr. C.) were mixed in a porcelain crucible. The crucible was heated by a Tirrell burner for five minutes, but the desired reaction did not take place. The calcium had oxidized. Another similar sample of calcium and carbon was heated in the blast lamp. After two minutes the reaction took place with violence, breaking the crucible. The contents were incandescent. Two portions of carbide were made in this way. It was of a greyish brown color and was hard and porous. The part in contact with the crucible was not collected. The rest was analyzed by the loss in weight method of Bamberger[4]. It was found to be 62 per cent. carbide. On boiling the sodium chloride solution in which the carbide was decomposed, after the addition of a little caustic soda, a strong odor of ammonia was noticed, showing that at the high temperature of the reaction, some calcium nitride had been formed.

Evidently, therefore, pure calcium carbide in any appreciable quantity cannot be produced by the direct action of carbon and calcium.

### THE ACTION OF CARBON ON CALCIUM HYDRIDE

The production of calcium carbide by the action of carbon on calcium hydride is also described very briefly by Moissan. The hydride was made by heating calcium turnings in an atmosphere of hydrogen in a nickel boat in an electric tube furnace. Ten grams of calcium was the largest amount used at one time[5]. The absorption of hydrogen by calcium started from 220° C. to 250° C. The temperature was gradually raised to 900° C., and held there until no more hydrogen was absorbed.

Eight separate portions of hydride were made; the first was pure white; the others were grey. In some cases the calcium alloyed with the nickel boat and had to be discarded. The hydride was crystalline and easily powdered. It was ground up and thoroughly mixed with an equivalent weight of carbon made from sugar and sulfuric acid. This was heated in the electric tube furnace.

The reaction which takes place is the following: $CaH_2 + 2C = CaC_2 + H_2$. The hydrogen was removed by a Richards pump and the pressure kept at about seven millimeters of mercury. The product obtained after several trials appeared white to the naked eye. When examined under the microscope the main part was seen to be white and transparent, except for crevices between the crystals which were apparently filled with uncombined carbon.

The analysis gave 103 per cent carbide. The cause of the apparent excess was found to be the presence of hydrogen sulfide, which was weighed as acetylene. The sulfur doubtless came from the sulfuric acid used for carbonizing the sugar. This shows how difficult it is to remove all the sulfur from carbon made in this way. Probably some of the acid is reduced to sulfur by its action on sugar.

The reaction between the hydride of calcium and carbon appears to begin at 50° C. as shown by the evolution of gas, which becomes rapid between 110° and 125°. This may, in part, be occluded gases of the carbon. The reaction appeared to be complete at 940° C.

The action of carbon made from acetylene on calcium hydride was next tried. The hydride was ground and passed through a sieve with 140 meshes per linear inch; 11.07 grams of this hydride were mixed with 6.292 grams of carbon by grinding the two together. One-third of this mixture was taken for a charge. This was placed in a nickel boat and heated in the tube furnace. The air was washed out by hydrogen before heating. On heating this mixture evolution of gas began at 30° as in previous runs, and continued as the furnace was heated to 1200°. (This was the temperature at the middle of the furnace; the ends of the boat may have been one hundred degrees cooler.) Even after holding the temperature at 1200° for an hour the evolution of gas still continued.

---

[1] C. R. 127, 917-18 (1898).
[2] Z. f. Elektroch. 10, 508 (1904).
[3] Thorpe, Dic. of App. Chem., Vol. 1, p. 25 (1912).
[4] Z. f. angew. Ch., 1898, 196.
[5] Moissan gives 15 grams as the upper limit. More metal may cause the temperature to rise to be sufficient to alloy the calcium and nickel. C. R., 127, 29 (1898)

The furnace was cooled without waiting for the gas evolution to be complete, and the charge examined. Except for a discoloration, the charge appeared unchanged; it did not react with water, and under the microscope the crystals of hydride could be seen, surrounded with the finer carbon. This showed that for some unexplained reason the carbon from acetylene does not react with calcium hydride to form calcium carbide.

The evolution of gas must be explained some other way. It may have been gas that was occluded in the carbon to start with or possibly the subcarbide[6] of calcium may have been formed: $CaH_2 + C = CaC + H_2$. The subcarbide does not react with water, but still this explanation does not seem probable.

The action of carbon made by heating sugar was also tried on calcium hydride. When mixed in equivalent quantities and heated in an electric tube furnace to 1000° C. in a vacuum, the product contained 28 per cent carbide. With a more intimate mixture the product contained 41.3 per cent carbide.

Pure calcium carbide cannot therefore be made in quantity by the action of carbon on calcium hydride.

### THE ACTION OF ACETYLENE ON CALCIUM AND CALCIUM HYDRIDE

When fine turnings of calcium were exposed to acetylene gas in a porcelain tube furnace at a temperature as high as 750° C., carbide was produced only on the surface of the turnings. The action of acetylene on calcium hydride was even less than on calcium.

### THE ACTION OF ACETYLENE ON CALCIUM DISSOLVED IN LIQUID AMMONIA

Finally Moissan's method[7] of passing acetylene into a solution of calcium in anhydrous liquid ammonia was tried. On passing acetylene into the blue solution the white precipitate described by Moissan consisting of $CaC_2 . C_2H_2 . 4NH_3$ appears and the solution loses its color. More calcium is then added and this may be continued until the required amount of carbide is obtained. (If the calcium is added to liquid ammonia in larger quantities a lustrous golden brown paste is formed.)

This carbide, however, is very reactive, due to its fine division, and the moisture of the air acts on it with such violence that the acetylene produced takes fire. According to Moissan the acetylene and ammonia are driven off at 150° C.

This method of preparing pure calcium carbide is, therefore, the only one of those tried that seems suitable for yielding it in sufficient quantity for experimental purposes. There is no difficulty in handling it as long as it is moist with ammonia. In introducing it into an electric vacuum furnace, for example, it would be necessary to have it covered with ammonia.

Some of the paste made by dissolving a large amount of calcium in liquid ammonia was allowed to stand in an atmosphere of acetylene. It gradually changed over into a grey powder which did not take fire in the air, and could be transferred to the furnace without any protection.

When heated to 150° it yielded a fine white powder, which when it was treated with water evolved an odorless gas.

### SUMMARY

Experiments are described, the object of which was to find a suitable method for making pure calcium carbide in quantities large enough for experimental purposes. The reactions between the following substances were not found to be suitable: carbon and calcium; carbon and calcium hydride; calcium and acetylene; calcium hydride and acetylene. The action of acetylene on calcium dissolved in anhydrous liquid ammonia was found to produce the desired result.

## Radium for the Masses

A Western assayer and chemist has received an important document from a genius whose letter-head announces that he is a dealer in "Dry Goods, Groceries, Hardware, Queensware." Evidently his activities are broader than indicated by his business, and scientific ability is being wasted in dry commercial pursuits. We quote *verbatim* from the letter:

> Dear Sir,
> I wish to take up small amount of your time to inform I have way to extract Radium from carnotite ore and get more out of it than heretofor.
> If your in position to send me 5 or 10 pounds of your ore from your state I will extract it and send you the Radium free of cost I want to find how rich your ore is by that way hoping to her of you.
>
> Yours Respectfully

Let the Bureau of Mines look to its laurels!

---

**Laboratory Apparatus and Reagents Catalog.**—The Arthur H. Thomas Company, of Philadelphia, Pa., has just issued its handsome new catalog entitled Laboratory Apparatus and Reagents, selected for laboratories of chemistry and biology in their application to education, the industries, medicine and the public health, including some equipment for metallurgy, mineralogy, the testing of materials and optical projection. It is a handbook of 660 pages, and embodies some really important novel features, particularly in the Reagents' Section. The first and by far the largest section deals with laboratory apparatus on 585 pages, brief, concise, illustrated descriptions being given of more than 12,000 different pieces of apparatus. The general arrangement is alphabetical, but in view of the mass of material described, a special alphabetical index of twenty pages at the end of this section is by no means superfluous. The reagents' section is the second section of the catalog and comprises seventy-four pages. In it 2300 different chemicals are listed alphabetically. The outstanding feature is that in the case of the chemically pure chemicals of Baker, Kahlbaum and Merck, the "typical analysis" of Baker, the "certified analysis" of Kahlbaum and the "guaranteed analysis" of Merck are given respectively, which facilitates greatly the selection of the most suitable brand in each case. The prices listed are the prices before the war started, and indicate, at least, the normal price basis for the reagents.

**The Miami Copper Co.** has officially announced the passing of the regular quarterly dividend payable November 16, 1914, due to conditions of the world's business and finance and the necessity of conserving the company's resources. The Boston News Bureau estimates that the passing or reduction of dividends by copper companies has caused a loss to investors at the annual rate of nearly $29,500,000.

**Production in the Cobalt district** increased in September as compared with August, and is now about normal. Temporary curtailment in August was due to uncertainty regarding the silver market caused by the war.

## Synopsis of Recent Chemical and Metallurgical Literature

### Copper, Lead and Zinc

**Electric Furnace for Melting Cathode Copper.**—The adaptability of the electric furnace to melting, refining and finishing purposes, and the disadvantages arising from the use of the reverberatory in melting cathode copper, have led Messrs. **D. A. Lyon** and **R. M. Keeney** to consider the possibility of electric melting of this material. Their original paper appears in the August *Bulletin* of the A. I. M. E. It is shown that so-called reverberatory refining of cathode copper results in deterioration of conductivity as compared with electrolytic copper which has not been melted, due to the introduction of impurities during melting. The ideal method would be one in which cathode copper would be melted and cast into marketable shapes without absorbing impurities. This would require a neutral process of melting such as could be done in an electric furnace. The authors discuss the types of furnace that might be used: (1) induction; (2) resistance; (3) direct arc; and (4) indirect arc. The conclusion is reached that the most practical furnace for copper melting would be the direct-arc type having a non-conducting hearth, like the Heroult steel furnace. In order to reduce possible volatilization to the lowest point it would be necessary to keep the metal covered with a slag while current is passing through the furnace. It is estimated that the power consumption would not be over 300 kw-hr. per ton of copper melted. Using this figure and basing other expenses on electric steel practice, the cost of melting cathode copper in a furnace of 25 tons capacity per charge should not exceed $4.75 per ton, or 0.238 cents per pound, of copper melted, with power at $\frac{1}{2}$ cent per kw-hr.

**Fuel in Reverberatory Copper Smelting.**—A valuable record of experimental work in reverberatory smelting is contained in the paper of **Mr. C. D. Demond** in the August *Bulletin* of the A. I. M. E. Experience with various fuels at Anaconda is given in detail, showing the requirements for a satisfactory reverberatory fuel. Four factors in coal affect smelting efficiency: 1, the character of the true coal substance; 2, the percentage of fine; 3, the percentage of moisture; and 4, the character and percentage of the ash.

In judging the character of the coal from proximate analysis a good deal of caution must be used, for the figures may be very misleading as to the ratio of fixed carbon to volatile matter in the real coal, and nothing can be told regarding the composition and quality of the volatile matter. Coal giving an opaque yellow or white flame due to incandescent particles is essential for success in reverberatory work. An excessively dense or smoky flame is not desirable. With coals that do not flame well under natural draft there may be a marked improvement under forced draft.

Furnace results are directly affected by the quantity of fine in the coal, the ratio of charge smelted to coal burned falling with the increase of fine coal. The best solution of the problem of fine coal is to pulverize all the coal and burn it by blowing directly into the furnace. This practice is growing in favor and has been adopted at some plants.

Moisture in the coal requires heat for its evaporation, and reduces the temperature of the furnace. The percentage reduction of the margin above the critical temperature reduces the capacity and economy of the smelting operation.

Ash also reduces the heating value of the coal, but has a value in preventing excessive loss of fuel through the grates. In some cases, however, the ash may clinker so badly as to clog the grate and interfere with combustion. It is seldom possible to predict from an analysis of the ash what its clinkering qualities will be.

Other factors affecting the efficiency of reverberatory smelting are the fluxing of the charge, preheating the charge and preheating the air. Mixing limerock flux with the calcine before charging to the reverberatory as against charging calcine and flux separately, has resulted in increasing furnace performance from 144 tons smelted with 46 tons of coal to 163 tons smelted with 48 tons of coal. Charging the calcine mixture hot also results in increased economy. Preheating the air in efficient heating devices has resulted in some cases in increasing furnace capacity 50 per cent over that obtained with cold air. The production of steam with waste heat from reverberatories at Anaconda makes about 25 per cent of the heating value of the total coal affective, while only 15 per cent is actually utilized for smelting. Power thus developed from eight furnaces amounts to 30 per cent of the 16,700 mechanical horse power used in the entire smelting and concentrating plant.

**Sinter-Roasting Processes Compared.**—A comparison of the Huntington-Heberlein and Dwight-Lloyd processes for roasting and agglomerating finely divided ores, is given by **Mr. W. W. Norton** in the August *Bulletin* of the A. I. M. E. Both systems of sinter-roasting are installed and in use at the Murray plant of the A. S. & R. Co., of which the author is superintendent. Five points of comparison are considered: cost of installation, cost of roasting, adaptability to wide range of materials, metal losses and physical condition of product. The author finds advantage in favor of the Dwight-Lloyd system on the first and third counts, in favor of the Huntington-Heberlein on the second and fifth, and is doubtful regarding the fourth. He gives results of furnace campaigns that show no advantage to reside in the physical condition of the Dwight-Lloyd product, either as to efficiency in reduction of the charge or speed of smelting. On the other hand he finds the Dwight-Lloyd excellently adapted to flexibility in the charge. No overwhelming advantage is found for either system.

**Recovery of Zinc and Antimony in Lead Refining.**—In the Parkes process for recovering the precious metals from base bullion, zinc is added to the molten lead in order to form an alloy with gold, silver and copper, which is removed by skimming. Antimony, if present, is not removed, and some of the zinc also remains. In order to remove these latter, air is blown through the molten mass, whereupon zinc and antimony oxidize, rise to the surface and are skimmed.

It has been found, also that the recovery of zinc and antimony from the desilverized bullion can be better accomplished in two stages. Zinc oxidizes first, and can thus be concentrated in a first skimming. The temperature is then raised, air is again blown through the bath and a second skimming removed which consists mainly of antimony.

At the Salt Lake meeting of the A. I. M. E., Mr. **Richard D. Divine** described a process for the treatment of this zinc-lead-antimony skimming, consisting in mixing it with sodium carbonate and pulverized oil coke, and heating in a reverberatory furnace on a bath of lead. Antimony and lead in the skimming are reduced and go into the lead bath, while zinc is volatilized as oxide.

The author suggests the possibility of applying the zinc-lead-antimony separation with sodium carbonate and coke, to complex zinc-lead ores after they have been roasted, and states that small-scale experiments seem to indicate a successful solution of the problem.

**Electrostatic Separation at Midvale.**—In Fig. 1 is given a flow-sheet of electrostatic separation of zinc-iron middling produced in the wet concentrator at Midvale, Utah. According to the latest data on this plant, presented by Mr. H. A. Wentwood at the Salt Lake meeting of the A. I. M. E., 1 pound of coal suffices for the evaporation of 5 to 7 pounds of water in drying the wet middling. By reference to the flow-sheet it will be seen that each unit in the separator produces three products: finished iron, finished zinc, and a middling which is returned to the screens. The potential used on the machines is 18,000 to 22,000 volts. One terminal of the potential line is grounded, as also are the machines. The other terminal is connected by highly insulated wire with the so-called attracting electrodes of the separators. An improvement in the machines consists in the substitution of metal for wooden electrodes, resulting in reducing the cost of maintenance 75 per cent.

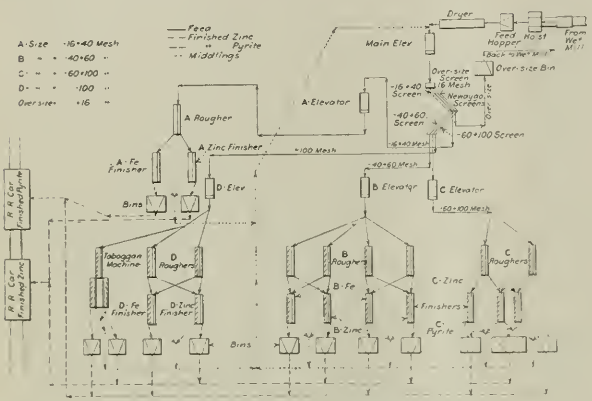

FIG. 1—FLOW SHEET OF ELECTROSTATIC MILL

**Lead Blast-Furnace Bosh.**—Commenting on the fact that blast furnaces frequently run better after they have been in blast for some time, and that furnaces with heavy crusts give remarkably clean slags, Mr. L. D. Anderson suggests that our standard shape of furnace is not ideal. In the November *Bulletin* of the A. I. M. E., Mr. Anderson states, with respect to angle of bosh, that "a rebuilt furnace of only about 10° or 11° has been running beside furnaces of the old angle of over 20°. As far as observed, the new furnace seems to run much hotter and obtain a larger percentage of lead contents as direct bullion output. The matte fall, however, is considerably smaller, and it is necessary to carry more sulphur on the charge in order to maintain this fall high enough to insure clean slags. . . . I feel that the matter of the correct furnace shape is yet far from being settled. Furnaces have been observed with crusts in them so heavy as to make it seem almost imperative to take them out of blast, whose slags nevertheless were so clean as to make the metallurgist reluctant to disturb them, until finally blowing out becomes imperative on account of the reduced tonnage. Experiences of this kind lead to speculations as to whether better reductions might not be obtained by making the shaft walls converging instead of diverging, somewhat after the lines of the iron blast furnace. In other words, why not make the furnace the ideal shape at the outset, instead of waiting for it to form its own 'natural' shape and running all the chances of irregularity in the formation of crusts?"

**Comparison of Huntington-Heberlein and Dwight-Lloyd Sintering Processes.**—In discussing a paper on this subject by W. W. Norton, presented at the Salt Lake meeting of the A. I. M. E., Mr. Arthur S. Dwight gives some interesting data in the November *Bulletin.* In regard to the reducibility of the products of these two methods of sintering, Mr. Dwight states that D-L sinter not only permits of economy of coke, but actually demands it. The fuel on a blast furnace charge must be proportioned to the work of reduction and melting. If some of these functions have been performed before the material enters the furnace, a corresponding allowance must be made if the fuel balance is disturbed. Since the iron in D-L sinter is present mainly as FeO, while in the H-H product it is as $Fe_2O_3$, there is less reduction to be accomplished with D-L sinter, and consequently less coke is required. As to range of sulphur in the charge, D-L machines can handle higher sulphur than the H-H pots. In regard to lead losses in the two processes, Mr. Dwight cites one plant at which the lead loss was 3 per cent in pots and only 0.75 per cent in D-L machines.

In discussing the same subject, Mr. G. C. Riddell states that at the East Helena plant of the A. S. & R. Co., where high lead charges are the rule and both D-L and H-H processes are used, the furnaces run at higher speeds and with lower coke consumption when dominated by the D-L sinter. Cost per unit of sulphur eliminated during 1913 was practically the same for both processes. Metal losses also were equal in both methods. A summary of Murray and East Helena experience with these two processes would appear as follows:

| | Advantage in Favor of | |
|---|---|---|
| | at Murray | at East Helena |
| Cost of installation......... | D-L | D-L |
| Cost of roasting............ | H-H | Even |
| Adaptability of charge .... | D-L | D-L |
| Metal losses ............... | Even | Even |
| Physical condition of product | H-H | D-L |

**Nodulizing Flotation Concentrates.**—In discussing the problem of nodulizing blast-furnace flue dust, in the November *Bulletin* of the A. I. M. E., Mr. James H. Payne gives some data on similar treatment of copper concentrates produced by flotation. Tests on Braden oil-floated concentrates were so successful as to lead that company to adopt the process. Fuel consumption is not over 6 gal. per ton, and in many cases is less. The flue dust produced by the kiln is practically *nil*, although some of the material treated has been as fine as 82 per cent minus 100-mesh. The amount of sulphur in the nodules is under control. The upper limit for good working seems to be about 15 per cent, but between 5 per cent and 15 per cent good work can be done. This makes pyritic blast-furnace smelting of concentrates possible. The size of the nodules varies; with a high sulphur product the nodules run smaller than with low sulphur. Nodulizing of sulphide concentrates, and pyritic smelting, opens a new and interesting field. The process is so cheap as to make it appear possible to compete with roasting and reverberatory smelting.

In the same discussion, Mr. R. M. Draper adds that nodules from El Cobre concentrates are satisfactory from a blast-furnace point of view, when charged cold. The nodulizing kiln could easily handle 60 tons of concentrates a day, and he believes it possible to increase this to 75 tons. In a screen test of nodules from El Cobre concentrates he shows over 95 per cent between 3 in. and 16-mesh, 2.5 per cent between 16 and 30-mesh.

### Gold and Silver

**Ore Treatment at the Chaffer's Mill, Kalgoorlie.**—A mill system said to represent the last word in the treatment of the ore at the southwest of the Golden Mile, Kalgoorlie, Western Australia, is described in the Aug. 5 issue of the Australian *Mining and Engineering Review*, by J. D. Connor. The ore is a hard, tough silica and softer quartz dolerite, containing precious metal irregularly disseminated in the free state, as telluride and locked in pyrite. The treatment method comprises dry crushing in Krupp ball mills to 100-mesh, followed by roasting in Edwards furnaces. The roasted ore is mixed with cyanide solution and ground in pans to a slime fine enough to pass 200-mesh. Amalgamation will be introduced at this point to catch any coarse gold. The slime will be thickened and agitated and filtered in a Ridgway vacuum filter. Precipitation will be by zinc shavings. Dry crushing is recognized as a dirty process, and provision is made against excessive dust by means of fans drawing dust from the ball mills and discharging it into a settling chamber.

### Concentration

**The development of the round table at Great Falls, Mont.**, presents an interesting example of the survival of one of the oldest forms of concentrating devices. The paper on this subject read at the Salt Lake meeting of the A. I. M. E. by Mr. Arthur Crowfoot gives the history of the round table and its development from the stationary Cornish buddle. Many experimental data also are given, showing the reasons for adopting this type of machine in an important position in the flow-sheet of a modern copper concentrating mill. The paper contains extensive experimental data on wood, linoleum, cement and canvas surfaces, and conical and conoidal decks. The author is of the opinion that the round table will continue to maintain its supremacy over other types of machines for the concentration of minus 0.07-mm. slime from the ores of the Butte district as long as wet mechanical concentration is the most satisfactory method of recovering the valuable minerals from that class of material.

### Smelter Fume Recovery

**Electrical fume precipitation by the Cottrell process** has been adopted at the Garfield smelter for the treatment of gases from the converters. The principal object is the recovery of lead fume. As described by Mr. W. H. Howard in the August *Bulletin* of the A. I. M. E., the process was adopted after experimenting with bag-house recovery as well as with the electrical process. Bags lasted only a few hours, due to the presence of an excess of unneutralized acid in the gases. One of the important developments of the experimental work on electrical precipitation was the adoption of iron pipes with axial wire electrodes in place of the regulation plates and pubescent electrodes which were first used at Coram, Cal. Another important development was the discovery that fractional precipitation of the constituents of the gas could be accomplished by successive treatments at different temperatures, the solid matter being precipitated at higher temperatures in one set of tubes and the acid, water and additional solids at a lower temperature in another set.

In Fig. 2 is shown a cross-section of the precipitating plant for converter fume. The converter gases will first pass through a 1000-ft. steel flue of 210 sq. ft. cross-sectional area, in which the cuprous material will be collected and the gases cooled. The precipitator consists of seven units containing 360 5-in. pipes, 10 ft. long, per unit. The gas velocity through the pipes will range from 9.6 to 12 ft. per second, according to the number of units in operation and the volume of gas delivered. Gases from the converter flue will enter chambers below the pipes, pass through them to the upper chambers and thence to the flue leading to the stack.

The electrical apparatus comprises seven complete motor-generator-rectifier sets and transformers.

A set consists of a 30-hp., 250-volt, direct-current motor, direct connected to a 20-kw., 4-pole, 60-cycle, 220-volt single-phase alternating-current generator. The 220-volt current is stepped up to 20,000 to 30,000 volts by means of a 20-kw. transformer and then led back to the rectifier, which is on the same shaft with the motor generator. Here it is rectified before going to the treater. The voltage before going to the transformer may be regulated to any desired value by varying the field excitation with a rheostat located at the switchboard.

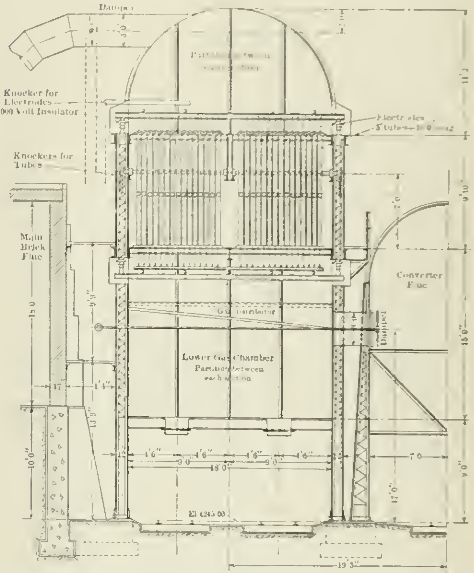

FIG. 2—CROSS-SECTION OF 360-TUBE UNIT FOR ELECTRICAL FUME PRECIPITATION

### Crushing and Grinding

**Laws of Kick and Rittinger.**—In his presidential address before the Chemical, Metallurgical and Mining Society of South Africa, published in the August *Journal* of the society, Prof. G. H. Stanley discusses the moot question as to the correctness of the laws of crushing promulgated by Kick and Rittinger. The author finds comparison of the two laws somewhat difficult "because the two laws do not deal with the same set of circumstances. Rittinger starts with a piece of ore of a certain size and compares the work done in breaking it into pieces of other sizes, while Kick, on the other hand, compares the work required to break, in a similar manner, pieces of ore of different sizes. In short, Rittinger refers to a constant total quantity, and Kick to a variable quantity." The author then proceeds from a mathematical discussion to deduce from Kick's law an expression of the same nature as Rittinger's, dealing with a constant total quantity. He finally arrives at this expression:

"The work required to reduce a given weight of rock from one size to another is proportional to the log of the $\frac{\text{initial}}{\text{final}}$ diameter." Analyzing his calculations, the author states: "Practically it shows that provided the degree of reduction is small, experimental results might almost be in accordance with the Rittinger theory, and this has undoubtedly given much support in the past. As the size of the particles diminishes, however, the increase of surface is much more rapid than the work required to produce it, and, as stated by Richards, this was experimentally found to be the case by Von Reytt; and though the latter's object was apparently to prove the correctness of Rittinger's law, his results, on the contrary, tend to confirm the deductions I have made from Kick's."

Based on the author's statement of the law, he makes comparison of the efficiencies of breakers, stamps and tube-mills. He does "not consider the data available are sufficient for the close comparison of our crushing practice with theory, and, hence, for an exact calculation of efficiency, since we have not available, for instance, the real average size of the final product, or indeed any of them, but by making some assumptions some interesting results are obtained."

He then assumes that the average size of feed to the different machines and the average size of their products are as follows: Breaker, 6 in. and 1½ in.; stamps, 1½ in. and 0.1 in.; tube-mills, 0.15 in. and 0.004 in. These figures give respective ratios of $\frac{\text{original}}{\text{final}}$ diameter of rock of 4.0, 15.0, and 37.5, the logs. being 0.602, 1.176, and 1.574, respectively.

"The efficiency of the three types is expressed as $\frac{\text{actual}}{\text{theoretical}}$ tons per horse-power. The theoretical can only be determined from the results of measurements of the work required to break known cubes, and this is not available; it may, however, be taken as a function of a constant *K*. In the three cases cited the theoretical tons per horse-power will obviously be inversely proportional to the theoretical work required, *i.e.*, as $\frac{1}{0.602} : \frac{1}{1.176} : \frac{1}{1.574}$ and is then a product of these figures, and *K*, *i.e.*, $\frac{K}{0.602}\ \frac{K}{1.176}\ \frac{K}{1.574}$, in other words, the breaker should crush more tons per horse-power than the stamps, and the stamps more than tube-mills; but unless the practical figures obtained are in the same ratio the efficiencies will not be equal. Assuming that the tons per horse-power per day in the three cases are 12, 4.5 and 2, the efficiency will be proportional to $12 \times 0.602$, $4.5 \times 1.176$, and $2 \times 1.574$ or 7.22:5.29:3.15, *i.e.*, efficiency is proportional to output per horse-power × log $\frac{\text{initial}}{\text{final}}$ diameter. Admittedly these figures can only be rough approximations for want of accurate data, and the subject is important enough to justify an extended investigation with the object of obtaining reliable figures. I think the average diameter is probably less than I have assumed, the error being probably greater in the finest size, which would tend to show the tube-mill, in the calculation, in a less favorable light than it deserves. Nevertheless, assuming they are not very far from the truth, it indicates that the tube-mill is considerably more efficient than it is considered to be in some quarters.

**Electric Precipitation of Fume.**—Supplementing the paper of Mr. W. H. Howard on electrical precipitation at Garfield, read at the Salt Lake meeting of the A. I. M. E., Mr. Edgar M. Dunn offers in the November *Bulletin* of the Institute some data on similar work at Anaconda. A feature of the work at Anaconda is the experimentation with large-diameter pipe treaters. Those at Garfield are but 5 in. in diameter, but at Anaconda 3-ft. and even 4-ft. pipe treaters have been tested. In the treatment of mixed roaster and converter gases 3-ft. pipes have been used, 20 ft. long, and good clearance has been obtained with a velocity of 5 ft. The single axial discharge electrode is No. 29 nichrome wire, and the current from 150,000 to 160,000 volts. Blast furnace gases did not give so good clearance, probably due to poverty in moisture and $SO_2$ as compared with roaster and converter gases. Tests will be made with 4-ft. treaters and voltage up to 220,000.

Fractional precipitation of gas constituents at successively lower temperatures has been used successfully in arsenic refining. Formerly it was the custom to volatilize arsenic from flue dust in two stages, the second being a refining stage to get rid of dust driven over in the first volatilization. It has been found that fractional precipitation, first at 310° C. and then at 90° C., gives two products, the first consisting mainly of the dust and the second of white arsenic 99.7 per cent pure. This will eliminate the necessity of two furnace treatments as heretofore.

**Tube-Mill End Liners.**—The following description of a combination wood and steel end liner for tube-mills is given in the August *Journal* of the Chem. Met. & Min. Soc. of S. Africa, by Mr. J. F. Pyles. The author states that the idea of using wood and steel for tube-mill liners is not original, but believes that its practical utility has not been proved previously with regard to end liners. The adoption of this liner arose from the necessity of installing one that would not fall out, and from the importance of economizing steel.

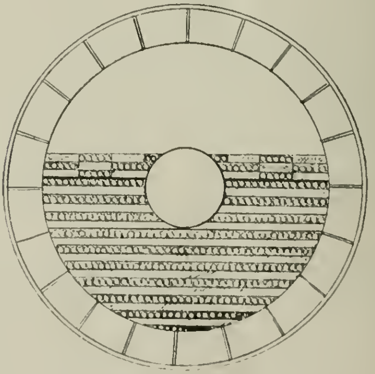

FIG. 1—TUBE MILL END LINER

As illustrated in Fig. 1, the liner is built around a sleeve 1½ in. thick. The annular outer portion is built of 6-in. chert blocks, and the intervening space of alternate courses of scrap steel cut in 6-in. lengths, pine boards 1 in. thick and 6 in. wide, and 6-in. pegs.

"The procedure in building the liner is as follows: First place the casting or sleeve in position, then build in the outer layer of chert blocks, which have been previously shaped to fit the mill. These blocks are placed in the mill with Portland or magnesite cement and keyed in position. A layer of 6-in. pegs is then put in with their axes parallel to the sleeve and their sides touching each other, and embedded in mortar. Next a board 1 in. thick and 6 in. wide, touching the chert circle at each end, is laid on the pegs and tapped into place. Mortar is placed on this board and the next row of pegs embedded in it, and so on until the liner is completed. The work of building this end liner will occupy one mason for half a day.

"The end has the following points to recommend it. It is inexpensive, both as to material and labor, and is quickly and easily installed. Owing to the wood absorbing the moisture from the cement, the end dries in a much shorter time than if only steel or chert were used. The swelling of the wood wedges the whole so tightly that all danger of the end, or any part of it, coming out is obviated.

"The life of the outlet end will be materially increased by staggering the wood and iron. This may be done by cutting the 1-in. board into pieces 6 in. square. Each row is then made by alternating 6 in. of steel with a 6-in. piece, and arranging the rows so that each piece rests on and is covered by steel. The pieces are placed with the grain of the wood parallel to the pegs."

### Chemical Engineering

**Cyanide from Coal Gas.**—Supplementing an article in our December issue, page 696, on Coal Gas Residuals, by F. H. Wagner, we present an excerpt from a paper on The Recovery of Gas Works By-Products, by C. C. Tutwiler, published in the October *Journal* of the Franklin Institute. The portion selected has special reference to the making of cyanide from coal gas.

"Cyanogen occurs in coal gas as free cyanogen $(CN)_2$, and hydrocyanic acid (HCN), both of which are gases. It is formed by the combination of a small percentage of nitrogen contained in the coal, with the necessary amount of carbon. The amount occurring in the gas is dependent upon the temperature of distillation, high heats being conducive to a high cyanogen yield. A temperature of about 1735 deg. F. is said to be most favorable. The yield of hydrocyanic acid will then be between two and three ounces per thousand feet of gas. It is rare in this country that as much as three ounces are produced owing to the comparatively low heat carried. Several heats made in an American gas works showed something over two ounces; being higher at one station than at another in the same works, due presumably, to slightly different heats carried. At works where no attempt is made to remove the cyanogen from the gas, about 10 to 15 per cent is taken out in the ammonia scrubbers, and the rest more or less completely removed in the purifiers, occurring there as Prussian blue. Up to a few years ago the spent purifying material was the chief source of cyanides, but it was soon recognized that only a portion of the whole could be recovered in this way and attention was given to its recovery from the gas itself.

"Numerous processes have been devised for wet scrubbing, the earliest being the Knublauch system, which consists in bringing the gas, by means of a mechanical scrubber, into intimate contact with a solution containing an alkali and the salt of a heavy metal, preferably iron. In this way soluble ferro cyanides are formed and recovered from the wash liquor by evaporation and crystallization. There were several defects in the Knublauch system and at present it has given way to other systems which are more efficient and more easily controlled. All of these, however, except perhaps the process exploited by the British Cyanide Company are based upon the Knublauch principle. A brief outline of the most important systems in use to-day is as follows:

"*Feld Process.*—In the Feld system, the cyanide washer is placed immediately after the ammonia scrubber, operating on gas freed from ammonia. The washer employed is usually of the standard rotary or bubbling type. Solutions of lime and ferrous sulphate are used as the scrubbing material, being introduced separately and continuously into the washer. The product obtained is a solution of calcium ferrocyanide, from which the pure salt can be crystallized.

"*Stavorinus Process.*—In the Stavorinus process the washer is placed immediately after the tar extractor and operates therefore on gas containing ammonia. The scrubbing material employed is a solution of potassium carbonate, and iron carbonate made from ferrous sulphate in suspension. The product obtained is a soluble alkaline ferro cyanide. Although the system is arranged for a continuous flow, the process is really intermittent. Two or three times a day a quantity of saturated liquor is drawn from the last bay of the scrubber and fresh liquor poured in. Since a large amount of ammonia is dissolved with the soluble cyanide, it must be recovered by boiling off in some form of concentrator. The residual sludge is then pumped into a filter, where it is converted into a clear solution and a cake, the solution consisting of potassium ferrocyanide, potassium sulphide and potash. This liquor is evaporated until it throws down the salt.

"*British Cyanide Process.*—In this process the gas is treated, immediately after the tar extractor, as in the Stavorinus process. A mechanical scrubber is employed having nine bays. Over eight of these bays is fixed a conical cup for holding the sulphur. Ammoniacal liquor is pumped into the washer at the outlet end, and granular sulphur is introduced intermittently into the eight bays. Ammonium sulphocyanide is formed and is disposed of as such.

"*Bueb Process.*—In the Bueb process, the cyanide washer is placed after the tar extractor. This process also operates on gas containing ammonia. A ferrous sulphate solution is employed as the scrubbing material. The product produced is a mixture of insoluble cyanides, which is sold in its crude state."

## Notes on Chemistry and Metallurgy in Great Britain

(*From Our Special Correspondent*)

### The Metallography of German Silver

In a paper communicated to the Chemical Society Mr. Frank Charles Thompson described a research of considerable interest carried out for the most part on actual commercial specimens of german silver subjected to ordinary works treatment and yielding results typical of the industrial alloys. The author remarked that almost the whole of the more directly industrially important knowledge of the copper-zinc-nickel alloys was contained in a paper by Hudson (J. Inst. Metals, 1913; i; 101), who, starting with the cast-steel metal traced its structural alterations on rolling and annealing; but only examined metal of one composition. Since these alloys consist entirely of Tafel's *alpha* solution (*Metallurgie*, 1908; Vol. V., page 419) they are metallographically strictly comparable with the *alpha* brasses. Further valuable information in M. Charpy's classical paper "Contributions a l'etude des Alliages" (Paris, 1901). Our present knowledge of the micrography of the german silver alloys might be briefly summarized as follows: The commercial alloys consist entirely of the *alpha* solid solution, since the appearance of the *beta* phase is accompanied by a brittleness that renders them incapable of receiving the work to which they must be subjected. In the cast state the structure consists of cored crystals, which in these nickeliferrous alloys are remarkably persistent under both mechanical and thermal treatment. Annealing at a proper temperature will in time remove this coring, giving place to a structure consisting of entirely allotrimorphic crystals in which, however, unless the annealing has been very prolonged, traces of the cast structure may still be recognized. Like all *alpha* solutions these alloys are rolled cold, which treatment produces, if carried far, an indefinite linearity in the direction of greatest extension. The cord structure often persists after repeated rolling and annealing. When the cold-worked metal is annealed above a certain (minimum) temperature a recrystallization is effected, the degree of coarseness of which is increased as the annealing temperature is raised and as the time is prolonged.

In dealing with the effects of deoxidants the author stated that in the photomicrographs of the aluminium alloy an incomplete network, faintly to be seen, might afford an explanation of the idea held by certain makers of german silver that the presence of even small amounts of aluminium is detrimental to the properties of the metal. He, however, found that the refining action of 0.25 per cent of manganese or 0.5 per cent of aluminium was remarkable, and was the more curious because, at any rate in the case of manganese, the whole amount added had passed into the slag, hardly a trace remaining in the alloy. The finer structure of the deoxodized alloys imparted to them a tensile strength higher than that of the untreated metal; and in view of the fact that no chemical difference existed between the treated and the untreated specimens, no explanation appeared to meet the case so well as that of the amorphous cement theory of the intercrystalline boundaries.

The author also drew attention to the following analogies between german silver and steel. In practice the annealing temperature-range from 900 deg. to 700 deg. is the same for each; and the temperature falls as the percentage of nickel increases in the non-ferrous alloys and as the carbon increases in the steel. In each case overheating will cause a reintroduction of the cast structure with an accompanying loss of ductility. The mechanical properties of german silver are not dissimilar from those of a normal mild steel. In each case, increased nickel content means a diminution in the size of the grain. The mechanism of the recrystallization after cold work appears to follow the same course for both metals. As shown by the austenitic steels the original cast structure of each is the same; and there is reason to believe that the peculiar persistence of the cored structure in german silver has a counterpart in the ferrous metals. The author's conclusions are: That the oxygen in german silver is probably present as finely disseminated oxide of zinc; that deoxidants have a marked influence in giving a finer crystalline structure accompanied by better mechanical properties; that a curious reproduction of the "as cast" structure has been found in burnt metal; that lead and tin both cause separation of distinct components, probably lead and a compound of copper and tin respectively; and, finally, that marked analogies exist between the metallography of german silver and steel, and between their mechanical and annealing properties.

### A New Gyroscopic Compass

Mr. E. Kilburn Scott and Capt. V. H. Rozie have devised a new form of gyroscopic compass which they have named the "Sea Star Type," and which was described and compared with the Anschutz and the Sperry instruments in a paper read before the Institute of Marine Engineers by Mr. Kilburn Scott. The author remarked that the Anschutz type of compass was of pendular construction and thus free to swing by the action of gravity. The Sperry gyroscope had a wire suspension, and was fitted with automatic "follow up" mechanism to prevent twisting of the wire by the movement of the wheel and to overcome friction about the vertical axis instead of this being performed by the gyro-wheel. The motor of the "following" mechanism also drove the compass card and transmitting gear, and so left but little work to be done by the wheel. It was an essential feature. The source of errors affecting instruments of these types is traceable to their being pendular and dependent on the force of gravity for their effectiveness.

The compass designed by Captain Rozie and himself did not depend on gravity for the magnitude of its righting momentum which was determined by the deflecting momentum to be counteracted; and this was effected automatically and forcibly. The gyro-wheel is not liable to ballistic disturbance in consequence of its being mounted with the horizontal axis non-pendular. They had in view the elimination of correction tables and mechanical correction, and also the production of a small, cheap compass which could be used on merchant ships and aircraft. The increased sensitiveness requisite in a small instrument had been attained by rotating the gyro-wheel in a direction opposite to that of the earth's axial rotation, so that the direction of rotation of the wheel was dextroroal when regarded from the northern side, with the consequence that the wheel was permanently in a state of unstable equilibrium. Then as soon as the slightest deflection occurred the tendency to increase deflection became very strong and caused the instant starting of the motor to remedy the deviation. Consequently the sensitiveness in meridian was very great, and the kinetic energy of the gyro-wheel became of less importance than it was in other instruments. In the Anschutz and the Sperry compasses the direction of rotation of the wheel coincides with that of the earth's rotation.

### The Tensile Properties of Copper at High Temperatures

Dr. G. D. Bengough and Mr. D. Hanson gave the results of their investigations of the effects of high temperatures on copper in various atmospheres. They found that the nature of the atmosphere was an important factor; and that an oxidizing atmosphere at high temperatures gave a high degree of ductility. In a neutral atmosphere, at all temperatures from 20 deg. C. up to 1000 deg. C. pure unannealed rolled copper retains all its superior strength as compared with annealed copper. With pure annealed copper fracture occurs through the crystals at all temperatures below about 700 deg. C., while at all higher temperatures above 750 deg. C. it occurs between the crystals; and between 700 deg. and 750 deg. it may occur in either way but has a preference for the intercrystalline path. Confirmation was obtained of the existence of a range of low ductility at temperatures about 250 deg. to 450 deg. C.

Small quantities of oxygen or of arsenic in copper have the effect of decreasing the tensile strength at high temperatures, but increased ductility has also been observed. In an atmosphere of hydrogen, at temperatures above about 720 deg. C., the test bars gave a tensile strength about half a ton per square inch lower than those tested in a neutral or an oxidizing atmosphere. The authors considered that this is probably due to reduction of copper oxide, which action might weaken the bars and ultimately cause cracking. As a whole, the results of the tensile tests are consistent with the theory of the crystals of copper being enveloped in a cement which at low temperatures is stronger than the crystals themselves but weaker at high temperatures; yet there are two points of interest which must at present be excepted from this explanation.

### Heating Alloys in Vacuo

A paper by Mr. W. E. Thorneycroft and Professor T. Turner gave some very interesting results of experiments carried out with the object of determining the effect of percentage of copper on the rate of the removal of zinc from copper-zinc alloys when suitably heated in a vacuum.

The authors arrived at the following conclusions:

Alloys containing upwards of 40 per cent. of copper can be separated quantitatively into their constitutent metals, but when the copper content is less than 40 per cent. some of the copper is volatilized with the zinc. Copper-zinc alloys which contain a high percentage of zinc are slightly more volatile than pure zinc, and it is probable that one particular alloy will be found to have the lowest temperature of volatilization out of the whole series of alloys. Alloys containing a high percentage of copper require for complete separation of the zinc a degree of heat decidedly greater than that requisite for the volatilization of the separated zinc.

### Electrolytic Iron

Among the papers presented for reading at the abandoned Paris meeting of the Iron and Steel Institute was one by Prof. L. Guillet dealing with the commercial production of electrolytic iron. The author stated that the Le Fer Company, of Grenoble, has taken out patents since 1910 for the electrolytic manufacture of iron. The method consists essentially in the use of a revolving cathode in a neutral solution of iron salts, the neutrality of which is maintained by constant circulation about the anode. Periodic additions of oxide of iron effect depolarization by partially removing hydrogen from the surface of the cathode, and permit the use of a current having a density as high as 1,000 amp. per square meter. From a solution made with ordinary pig iron a product can be obtained of a very high degree of purity. After removing occluded gases by annealing the metal contains an average of only 0.004 per cent. of carbon, 0.007 per cent. of silicon, 0.006 per cent. of sulphur and 0.008 per cent. of phosphorus. When taken from the bath the metal is hard, very brittle and contains occluded gases, notably hydrogen. Sir Robert Hadfield obtained 28.8 cc. of gases from a sample of the iron weighing 34 grammes, having a volume of 4.33 cc., by heating it in a vacuum for four hours at 800 deg. C. to 1,100 deg. C. and for two hours more at nearly 1,400 deg. C. The relative volumes of the gases were, hydrogen 18.8, carbon monoxide 7.4, carbon dioxide 0.2 and oxygen 2.2. The Brinell hardness of the crude iron is 193 with a ball of 10 mm. in diameter and a load of 3,000 kg., and the micrographic structure is composed of exceedingly numerous fine needles, closely resembling martensite. Annealing in magnesia for two hours at 900 deg. C. reduces the Brinell hardness to 90 and imparts a perfectly normal micrographic structure.

Tensile tests on tubes gave a breaking strength of 30.9 to 32.8 kg. per square millimeter (about 20 tons per square inch), with an elongation of 40.2 to 42.1 per cent. in the direction of the axes. Annealed tubes withstand compression tests producing more than ordinary deformation without exhibiting any sign of fracture. One tube 100 mm. in diameter and 0.75 mm. thick when subjected to a pressure of 1,200 lb. per square inch showed a deformation as regular as if it had been squeezed in a press. Another portion of the same tube was exposed for 2½ months to a temperature of 120 deg. in a steam boiler and then withstood a pressure of 1,200 lb. per square inch without any sign of fracture being perceptible.

Tubes are being manufactured by Messrs. Bouchayer and Viallet, whose plant is equal to an output of 100 lengths per day. The tubes are uniformly 4 metres long, and vary in diameter from 100 mm. to 200 mm. and in thickness from 1 mm. to 6 mm., and the great regularity in the thickness obtained contrasts strongly with the inequalities prevailing in the tubes made in the ordinary way, particularly when the thickness is less than 6 mm. The manufacture of sheets is still in the experimental stage, but hopes are entertained of their direct production without rolling. The quality of the iron is first rate, and as it can be worked with remarkable facility, it is especially suitable for stamping both as black annealed plate and as tinplate. The great purity of the sheets endows them with a particular value in the construction of electrical machinery by reason of the increased efficiency to be secured and the reduction in the weight of the material to be effected.

For the manufacture of steel the electrolytic iron appears likely to compete quite successfully with the best Swedish iron. Its quality is very regular, and its brittleness enables it to be broken into small pieces of any required size, and consequently it lends itself to a more uniform cementation than does ordinary material. Tool steel and special steel giving results at least equal to those obtained with similar steels made from Swedish iron have already been produced at several steel works. Working with a current density of 1,000 amp. per square meter a yield of two tons of very pure iron per kilowatt-year is obtained; but when the density is reduced to 500 amp. per square meter the output per kilowatt-year is nearly doubled, and on the latter basis the total cost of production, making ample allowance for waste of pig iron, depreciation, etc., is estimated at from £6 to £7 12s. per ton, according to local conditions.

### Electrolytic Iron

It appears that the process for the production of electrolytic iron in tubes and sheets described in the paper by Prof. L. Guillet had, according to a statement in the *Times*, already been worked out in England by Mr. S. Cowper-Coles, and that works are to be erected in the Midlands for the commercial manufacture of sheets, tubes, etc. In 1908 Mr. Cowper-Coles read a paper before the Iron and Steel Institute in which he gave details of the electrolytic production of finished iron tubes and sheets in one operation. In his process he employed a mandrel revolving at a critical speed in order to give sufficient "skin friction" between the electrolyte and the deposited metal to obtain a close homogeneous deposit and to permit the use of a high-current density, whilst the solution was kept neutral by circulation over the anode. In the following year a license was granted to Mr. Boucher to work the process in France and Switzerland, and a small trial plant was put down in Switzerland with which a number of tubes was produced. The Compagnie Le Fer was subsequently formed to acquire this license. (The Cowper-Coles process was described in detail in a paper by Messrs. W. Palmaer and J. A. Brinell in our issue of April, 1913, Vol. 11, page 197.)

### The Influence of Coke on Corrosion

The paper by Mr. Arnold Philip, an abstract of which was given in last month's letter (page 724), which expressed views and quoted results quite opposite to those given by Dr. Bengough and Mr. Jones in their report to the corrosion committee of the Institute of Metals has called forth an energetic reply from those gentlemen. They expressed surprise that the results of Mr. Philip's researches should have been so completely contrary to those obtained in their own investigations, and decline to admit that the contact of coke with condenser tubes in seawater induces electrochemical action. They point out that Mr. Philip carried out his experiments under conditions essentially different from their own tests; and that, consequently they propose to undertake further investigations, as at present there is uncertainty as to how the variation of conditions affects the results. In reply to Mr. Philip's definite assertion that in all his experiments, without exception, he found that the presence of coke caused accelerated corrosion, and also apparently dezincification in two days in seawater at ordinary temperatures with accelerated action at higher temperatures. They state that in no case did they observe dezincification in less than seven days at 50 deg. C., or about seven months at ordinary temperatures, whether coke were present or not.

### Water Softening

The results of a series of experiments are recorded by Mr. W. Buscoe Baron in the Manchester paper *Vulcan*. In summarizing the results he considers the importance of bringing water to which softening chemicals are added, intimately in contact with crystalline calcium carbonate to be the means by which the lowest results are obtained. He points out that every effort should be made to soften the water without involving excess of alkali. The experiments dealt with lime permanent hardness.

### Market Prices

*October*, 1914.

| | | £ s d |
|---|---|---|
| Aluminum ingots, ton lots | | 88. 0. 0 |
| Alum, lump, loose per ton | £5.5.0 to | 5.10. 0 |
| Antimony, black sulphide powder, ton | | 23. 0. 0 |
| Borax, British crystal, cwt | 18/6 to | 19. 6 |
| Copper sulphate, ton | | 22. 0. 0 |
| Caustic soda, 70 per cent, per ton | 9/9 to | 10. 3 |
| Copper ore, 10 to 25 per cent, unit | | not fixed |
| Ebonite rod, lb | | 3. 0 |
| Hydrochloric acid, cwt | | nominal |
| India rubber, Para, fine, lb | | 2. 7½ |
| Mica, in original cases, medium | 3/— to | 5. 0 |
| Petroleum, Russian spot, gal | | not fixed |
| Quicksilver, Spanish, bottle | | 10. 5. 0 |
| Sal-ammoniac, cwt | | not fixed |
| Sulphate of ammonia, ton | | 10.10. 0 |
| Shellac, per cwt | | 3. 0. 0 |

The Metal Exchange remains closed; prices are therefore approximate.

*Copper*—Best selected copper was fixed at £56.5 to £56.15. on the 6th, £55.10. to £56 on the 9th, and closed at £54.5. to £55. Copper has been obtainable at £52.10.

*Tin* opened at £134 to £136, and was harder in the third week. From the 16th to the end of the month it was £133.

*Haematite* opened at 66/-. On the 16th was 66/- at Glasgow, and the same on the 23rd, but had fallen to 62/- by the 30th.

*Scotch Pig*—Closes at 55/4½d.

*Cleveland*—Opened at 50/11; selling at 50/0½ on the 9th, subsequently went lower. Rose a little on the 19th to 49/6½, afterwards becoming quieter and closing at 49/-.

*Lead*—Opened at £19.15. and closed at £18.10.

**American Peat Society.**—The 1915 meeting of the American Peat Society will be held in Detroit, Mich. Mr. Carl Kleinstück, of Kalamazoo, Mich., is the president, and Mr. Julius Bordollo, Kingsbridge, N. Y., the secretary of the American Peat Society.

**Thermit in a Municipal Repair Plant.**—The repair shop connected with the Bureau of Water, Department of Public Works, Philadelphia, Pa., has adopted thermit for heavy repairs. Some repairs carried out in this shop are the subject of an interesting illustrated article in issue 3, 1914, of *Reactions*, published by the Goldschmidt Thermit Company, of New York.

## Recent Chemical and Metallurgical Patents

### Iron and Steel

**Briqueting Iron Ores.**—The use of tar, from which water and the light and middle oils have been removed, is suggested as a suitable binder for iron ores, in a patent granted to Mr. Georg Crusius, of Gross-Ilsede, Germany. The inventor claims that the use of ordinary soft tar is not advantageous on account of its content of light oils that distill out of the briquets when subjected to the heat of the furnace; but the use of specially prepared tar is without these objections and gives good results. (1,116,024, Nov. 3, 1914.)

**Cooling Open-Hearth Furnace-Ports.**—A mechanism for cooling the arches and maintaining the gas ports of metallurgical furnaces, patented by Mr. Frank E. Parks, of Pueblo, Colo., consists in a port structure comprising a water-cooled frame of separate hollow cooling elements. Each cooling element is provided with several conduits for supplying a cooling fluid, and provision is made for maintaining a circulation through one or more conduits while others may be inactive. (1,113,245, Oct. 13, 1914.)

### Copper, Lead and Zinc

**Extracting Copper from Carbonate and Oxide Ores**—In several patents recently granted to Henry R. Ellis, of Salt Lake City, Utah, he amplifies a process of extracting copper from carbonate and oxide ores by solution with carbonate or bicarbonate of sodium or potassium, and electrolysis of the solution. The present invention specifically makes use of a mercury cathode and insoluble anode. It is claimed that when using a mercury cathode a current density may be used of many times that permissible when copper is the cathode. The ore is crushed in solution to a thin slime and conveyed to the electrolytic vat where the copper is precipitated. The slime is kept in suspension by agitation. One method of using the mercury cathode is shown in Fig. 1, in which the vat $T^3$ contains a revolving shaft $S^2$ carrying wheels $a^3$ with an iron anode cylinder $A^3$ of perforated sheet metal or woven wire. Around this cylindrical anode is arranged the concentric cathode of amalgamated copper, connected with the cylinder $A^3$ by non-conducting radial supports *r*. The cathode revolves in a bath of mercury $m^3$. (1,115,521-2-3, Nov. 3, 1914.

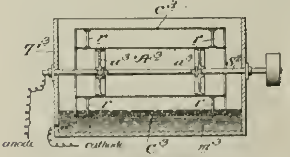

FIG. 1—ELECTROLYSIS OF ALKALINE COPPER SOLUTION

**Heating Leaching Solutions.**—A method of heating copper leaching solutions by the heat absorbed from water used in ore-coolers, is patented by Frederick Laist, of Anaconda, Mont. The idea is illustrated as applicable to a form of ore-cooler patented by Mr. Laist and reviewed in this journal, May, 1914, page 352. In that cooler the hot ore is cooled by means of water pipes extending the length of a drum, entering at the point of ore discharge. The hot water issuing from these pipes at the end of the drum at which hot ore is charged, is then led to a tubular heater where its heat is transferred to a leaching solution. The latter flows through the tubes of the heater, which are surrounded by the hot water from the cooler. (1,115,689, Nov. 3, 1914.)

**Furnace for Producing Lead Pigments.**—In the manufacture of lead pigments, for example minium, or red lead, accurate control of conditions in all parts of the furnace is an essential. To secure this control of Mr. Clifford D. Holley, of Detroit, Mich., has designed and patented a reverberatory furnace with a pair of grates at opposite ends of the hearth, and a number of waste-gas exits at different points above the hearth, so that the course of the flame and fire gases over the hearth can be changed at will. The firing may be by any of the usual means—coal, coke, gas or oil. The furnace has charging and discharging doors at back and front, respectively. (1,116,703, Nov. 10, 1914.)

**Retort Discharging Machine.**—In Fig. 2 is shown a side elevation of a machine patented by John J. Simmonds, of Iola, Kans., adapted to the operation of discharging zinc retorts after the distillation process is complete. It comprises a number of mechanically driven elements arranged to enter the retorts of a furnace and clean them out. The elements consist of endless chains moving over sprocket wheels and carrying scrapers which progressively remove the residue from the retorts simultaneously with the advance of the elements. The machine is mounted on a car movable along a track in front of the furnaces. (1,110,081, Sept. 8, 1914.)

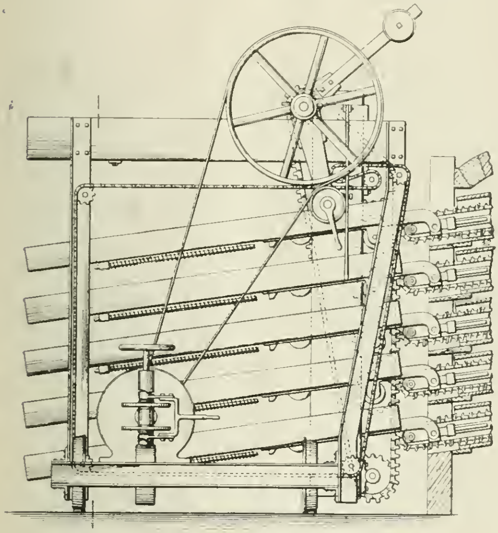

FIG. 2—RETORT DISCHARGING MACHINE

**Recovery of Zinc from Refuse.**—The prevention of metal loss in the zinc-bearing refuse of brass foundries and rolling mills is the purpose of a process patented by Mr. Ralph R. Parish, of Waterbury, Conn. The material is gradually introduced into a tank containing a 1 per cent to 5 per cent solution of sulphuric acid. The mixture is continuously agitated with compressed air, and when the density of the zinc solution has reached from 30° to 45 Baume the remaining acid is neutralized by the addition of an excess of zinc-oxide refuse. This precipitates iron, and agitation is continued until all iron has been removed from solution. If manganese is present ozonated compressed air is used to convert that metal into an insoluble oxide. Freed from iron and manganese, the zinc solution is either decanted or filtered. It still contains such impurities as cadmium and copper, but these are removed by precipitation with zinc in the form of dust or shavings. The resulting pure solution of zinc sulphate is then evaporated to crystallization or electrolyzed to produce pure zinc metal. (1,104,922, July 28, 1914.)

**Apparatus for Isherwood Zinc Process.**—In Fig. 3 is shown an extracting and filtering apparatus patented by Mr. Percy C. C. Isherwood, of Bushey Heath, England, for the treatment of refractory zinc ores. It consists of a longitudinal casing mounted on rollers and adapted to be revolved. A central partition extends the length of the casing, dividing it into two separate parts, each with manholes as shown. On each side of the central partition is a filter with suitable outlets for discharging filtered solution. The charge of ore and solvent is introduced into one compartment of the casing, and steam is forced in under pressure, thereby heating the solution to a high temperature. The casing is then revolved until this compartment is lowermost, and may be reciprocally moved in that position to aid in solution of the metal. In the meantime the upper compartment is being charged. When the treatment of the first charge is complete the casing is rotated 180 degrees, whereupon the coarse particles in the first charge fall on the filter and underly the finer particles. Filtration of the solution can then proceed under the internal pressure generated by the steam. After filtration the casing is again rotated and the tailing discharged through the manholes. Both compartments are alternately in use in different stages of a complete cycle of treatment, effecting economy in time and space. The process has been tried in an experimental plant at Perth Amboy, N. J., and it is stated that experiments with it are to be continued on a larger scale at Keokuk. (1,110,790, Sept. 15. 1914.)

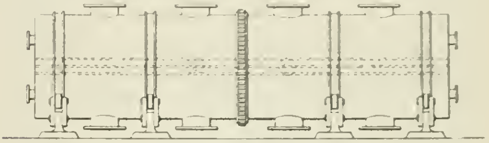

FIG. 3—ISHERWOOD ZINC DIGESTER AND FILTER

**Electric Zinc Furnace with Integral Condenser.**—A resistance furnace for the reduction of zinc oxide obtained as a product of igneous concentration is shown in section in Fig. 4, being the invention of Mr. Charles V. Thierry, of Paris, France. The heat is derived from the passage of a current through a resistor H of broken carbon resting on the hearth of the furnace between carbon terminals D, D′. The charge J rests on the resistor. The walls of the furnace adjacent to the longitudinal sides of the resistor, and the sole or hearth of the reaction chamber, either or both, form the condenser. Slots or crevices 6 in the walls and hearth provide for the evacuation of the gases and

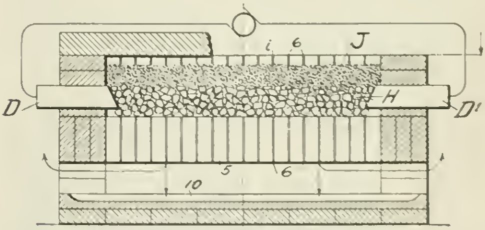

FIG. 4—ELECTRIC ZINC FURNACE WITH INTEGRAL CONDENSER

metal fumes, the latter being condensed and collected in an underlying receptacle 10.

In the beginning of an operation the gases evolved escape through the numerous fissures and, being under some pressure, will prevent the entrance of air. They will also assist in progressively heating the sidewalls of the fissures. The inner faces of the walls will become heated to the temperature of the resistor, and will be heated by conduction in a progressively diminishing ratio toward their outer surfaces. The inventor is of the opinion that these conditions are favorable to the condensation of zinc. ( (1,110,359, Sept. 15, 1914.)

**Sintering Zinc Retort-Residues.**—The preparation of zinc retort-residues for the recovery of their precious metal contents by smelting in the blast furnace is accomplished by burning them in heaps or piles, utilizing their contained coal as fuel. As outlined in the patent on the process granted to Mr. ARCHIBALD JONES, of Bartlesville, Okla., the beneficial effect of this treatment is three-fold: the carbon is eliminated, thereby reducing the weight and consequent cost of freight; the zinc content is greatly reduced, the sublimed zinc being condensed in the outer layer of the pile and subsequently recovered for retort reduction, and the material is sintered into a mass which, on being broken to suitable size, makes a good blast-furnace feed.

The residues are taken from the retorts and deposited on the ground over a system of trenches or flues made of fire-clay tile. One end of the main flue is connected with a source of air-blast of about 1 ounce pressure per foot of residue in the pile. Fuel may be used at points in the flue system in order to initiate the ignition, but ordinarily the 30 to 40 per cent of fuel in the residue is sufficient for combustion. As combustion is propagated throughout the mass, zinc is volatilized and condensed in a surface crust, which is removed and resmelted. The finished sinter is practically free from carbon and zinc, and can be smelted for recovery of other metals. (1,112,-010, Sept. 29, 1914.)

**Manufacture of Zinc Oxide.**—In a patent granted to Mr. J. A. SINGMASTER and assigned to the New Jersey Zinc Co., the inventor discloses a scheme for producing zinc oxide in a continuous operation. The process is claimed as an improvement on the Wetherill process using stationary grates. According to the invention the charge of ore and fuel is placed on a moving car, forming a traveling grate which advances through the combustion zone where the reactions take place with uniform combustion and complete utilization of all the valuable elements of the charge. Fig. 5 gives an idea of the furnace with its several flues for handling the gases evolved at different stages of the process.

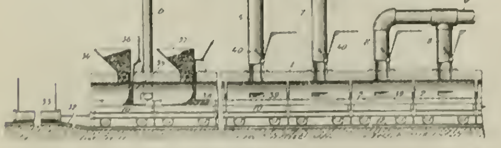

FIG. 5—CONTINUOUS PROCESS FOR MAKING ZINC OXIDE

The tunnel is of masonry, about 150 ft. long and 7 ft. by 6 ft. internal cross-section. The interior is provided with a series of partitions 2, depending from the roof and serving as baffles to prevent movement of gas between the combustion zone and the ends of the tunnel. From the pockets formed between these partitions leads an off-take for the gas or fume. These permit the separate disposal of the metallic and non-metallic fumes that come from a charge at different points in the tunnel. The first, as at 5, is for the non-metallic gases which may be used for fuel, being distillation products from the coal. The next, 7, is for the first metallic fume which may be of poor grade and not suitable to be mixed with the finest product of the furnace. The others, as at 8, are for the zinc oxide that is produced when the process is at its height, and are combined in a long flue 9, leading to the bags. Details of mechanical construction are given in the patent specifications. (1,112,853-54, Oct. 6, 1914.)

## Tin

**Detinning Process.**—The removal of tin from tin-coated metal may be accomplished by treatment with a slime containing a solution of a tin salt and gray tin, according to claims in a patent granted to WALLACE SAVAGE, of Piedmont, Ala. He claims to have discovered that a coating of ordinary white tin may be changed to a dark, amorphous, nonadherent powder known as gray tin by the catalytic action of gray tin, and that the change takes place most satisfactorily when gray tin is employed in connection with a solution of a tin salt, preferably tin ammonium chloride, known as "pink salt." The reaction occurs at ordinary temperatures, but is preferably brought about below a temperature of 68 deg. F. The slime is produced by dissolving 10 lb. of tin ammonium chloride in 100 gal. of water and mixing with this solution about 2500 lb. of gray tin. On application of this mixture to tin-coated metal, the tin is separated as an amorphous powder. (1,113,491, Oct. 13, 1914.)

**An improvement in detinning** by means of chlorine, using a mixture of air and chlorine, is patented by GUSTAV VON DER LINDE, of St. Tönis, near Crefeld, Germany. It consists in producing a uniform mixture of air and chlorine of suitable concentration by means of diffusion, and then allowing this mixture to act on the metal to be treated. The method of securing the uniform mixture is to pass chlorine into a chamber charged with distributing bodies filled with air, as for example Guttman's hollow balls. After the chlorine fills the chamber containing these bodies, air rapidly diffuses into the chlorine and forms a uniform mixture which is then distributed over the metal to be treated. By reduction of the pressure caused by the formation of tin chloride, air is again drawn through a seal into the distributing bodies so that the process of uniform dilution can be repeated. The process is performed in apparatus shown in Fig. 6, in which *a* is a receptacle charged with tin scrap, and which communicates with a chamber *d* through holes in the receptacle *a*. The chamber *d* is connected with chlorine supply pipes *b*

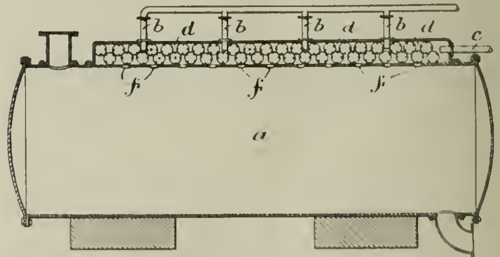

FIG. 6—APPARATUS FOR DETINNING

and a pipe *c* that leads to an acid seal. The chamber *d* is charged with hollow distributing bodies *f*. Chlorine is intermittently supplied to the chamber *d*, mixed with the air of the distributing bodies and finally admitted to the chamber *a*. When the pressure in the latter is reduced by the reaction, air is drawn into the chamber *d* through the pipe *c*, so that the distributing bodies again become filled with air. (1,116,176, Nov. 3, 1914.)

### Rare Earths

**Electrolytic Separation of Rare Earths.**—In describing a method for fractionally electrolyzing solutions containing yttrium, erbium, thorium, cerium and zirconium, Louis M. Dennis, of Ithaca, N. Y., states that heretofore experiments on such separation have failed due to the fact that the compounds formed by electrolysis have adhered to the electrode in such manner as to increase the internal resistance of the cell to a point where appreciable separation was impossible. He has discovered that if the surface of the cathode be kept free from adhering deposits, the elements referred to may be fractionally separated in the form of compounds, such as hydroxides. In the preferred form of apparatus he uses a glass cell with a mercury cathode and platinum anode. The following example of electrolysis is cited: 25 grams of the oxides of the yttrium group of rare earths may be dissolved in nitric acid and evaporated to dryness. The residue is taken up with 500 cc. of water and electrolyzed for 6 hours at 9 volts. At the end of that time a precipitate of hydroixide is formed which is removed by filtration. The solution is then again electrolyzed under the same conditions, when a further precipitate is formed and removed. The process may be repeated for the number of fractions desired. Examination of the two fractions shows that a rapid and quite complete separation of yttrium from erbium has been effected. (1,115,513, Nov. 3, 1914.)

### Ore Cooler

**Apparatus for cooling roasted ore** is shown in Fig. 7, being the invention of Robert W. Hanington, of Denver, Colo. It consists essentially of two concentric cylinders mounted on a hollow shaft supported in an inclined position. The inner surface of the outer cylinder and the outer surface of the inner cylinder are provided with Z-shaped flights which serve to catch the ore fed into the space between the two cylinders and distribute it over their surfaces during the rotation of the machine. Water is distributed over the outer cylinder from a launder supported above the cooler, and is sprayed over the inner surface of the inner cylinder through perforations in the hollow shaft. During the rotation of the machine the ore passes from the feed to discharge end due to the inclination of the cylinders. (1,101,433, June 23, 1914.)

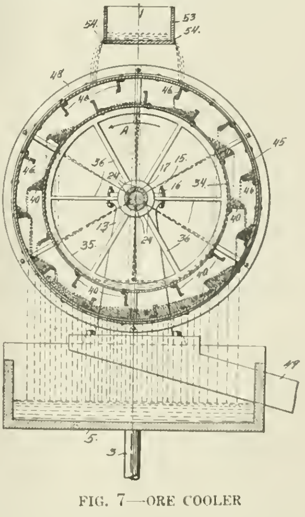

FIG. 7—ORE COOLER

## Zirconia, a New Refractory

BY H. CONRAD MEYER

Among the numerous so-called rare elements, zirconium has, to within the last few years, ranked as technically unimportant. The development of the electric furnace, requiring for its construction bodies having an extraordinarily high degree of refractoriness, has probably been an important factor in calling the attention of the electrometallurgist to the possibilities of zirconia.

In the year 1788, the German mineralogist, M. H. Klaproth, while engaged in the analysis of the mineral zircon, discovered that apparently 68 per cent of the mineral consisted of a very inert substance differing in its properties from all other substances known at that time, and which he ultimately determined to be the oxide of a new element. Having been first recognized in the mineral zircon, the name zirconium was proposed and ultimately adopted.

The element zirconium in the free state occurs in three forms: amorphous, crystalline and graphitic. It has a density of 6.4 in the crystalline form, with a melting point of about 2350 deg. C. As the element has no important use in its uncombined state at the present time, we will not dwell further upon its properties. It is not as rare as commonly supposed, having been determined by careful calculation to constitute 0.03 per cent of the lithosphere,[1] about as plentiful as the element carbon.

*Sources.*—At the present time there are only two known minerals which occur in sufficient quantities to be considered as commercial sources of zirconium. The first of these is the natural oxide zirconia; the second, zircon or the silicate. As zirconium oxide is generally the starting point for all zirconium compounds, the natural oxide is thus more eminently fitted as a commercial source than zircon. As found in nature, natural zirconia carries about 84 per cent of the pure oxide, with about 8 per cent silica and 3 per cent iron oxide. There are several methods in vogue for the extraction of the pure oxide, the best known being that of fusing the natural substance with sodium carbonate or hydroxide, thus producing sodium zirconate, which on being leached is hydrolized, forming soluble sodium silicate and insoluble zirconium hydroxide. The precipitate after thorough washing, can be readily converted into soluble salts by treating with any of the strong mineral acids.

*Refractory Properties of the Pure Oxide.*—Refined zirconia is a pure white substance, having a density of about 5 and a belting point of 3000 deg. C., according to Weiss. The first important use found for the oxide was to replace the calcium oxide cylinders used in the Drummond or so-called lime light. The great objection to the calcium oxide was its rapid deterioration, owing to its absorption of moisture and carbon dioxide from the air. Besides giving a more intense illumination, zirconium oxide was absolutely unaffected by moisture or any of the atmospheric gases.

Later, in 1880, R. von Welsbach impregnated loosely woven cotton or linen fabric with zirconium nitrate, securing a skeleton of zirconium oxide by incineration. The form of the fabric, thus perfectly preserved, became highly incandescent when heated in the flame of an ordinary Bunsen burner. Subsequent experiments proved, however, that thorium gave the same results at a much lower temperature. Therefore, it has almost entirely replaced zirconium for this purpose. These experiments of von Welsbach mark the inception of the incandescent gas mantle industry.

---

[1] Data of Geochemistry, F. W. Clarke, Bulletin 491, U. S. Geological Survey.

The next important application of the pure oxide occurred in 1897 in the Nernst light, developed through the behavior of certain refractory oxides, which, when heated to a high temperature, become excellent conductors of electricity and glow with an intense white light. This lamp consists essentially of a number of small rods or "glowers" composed of magnesia, zirconia and yttria. By a suitable heating device, the glower is raised to a temperature of 634 deg. C., at which point current begins to flow, raising the oxides to incandescence. As the quantity of zirconia used in the Nernst lamp is comparitively small, no great commercial application can be looked for in this quarter.

The remarkable heat-resisting qualities of zirconia at once commended it as a refractory of the first order. Its high melting point, low coefficient of expansion and low thermal conductivity, make it apparently the ideal lining for electric furnaces of the arc type. The pure oxide, owing to the comparatively high cost of extraction, is too costly a material for industrial uses on a large scale. Careful tests have shown, however, that natural zirconia is eminently fitted for such work and has only a slightly lower efficiency.

Very remarkable heat-resisting ware, such as crucibles, muffles, pyrometer tubes, combustion boats and resistance cores for electric furnaces, can be manufactured from pure zirconium oxide mixed with from 3 per cent to 10 per cent magnesia, using starch, phosphoric acid, glycerine or borates as binders. The ware is dried for several days at a low temperature and then fired in the electric furnace at a temperature ranging from 2000 deg. to 2300 deg. C. This ware is practically impervious to liquids, and is not affected by strong acids or alkali fusion mixtures.

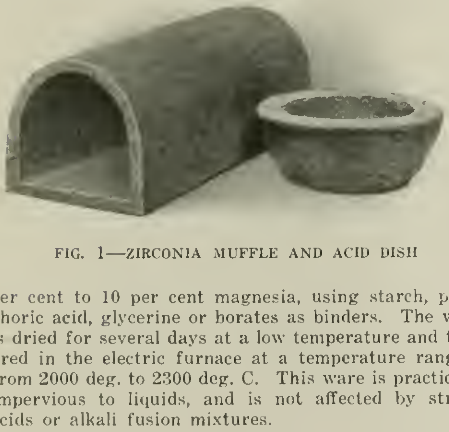

FIG. 1—ZIRCONIA MUFFLE AND ACID DISH

Owing to the extremely low coefficient of expansion, zirconia ware can be subjected to very sudden changes of temperature, such as plunging a red hot crucible in water, without the slightest danger of fracture.

The fusing point of tungsten alloys and the boiling point of pure iron, according to recent investigations,[2] have been successfully determined in zirconia crucibles.

The cost of the pure oxide for the manufacture of such articles as the foregoing and other ware requiring a maximum resistance to heat and corrosive action, is at the present time not prohibitive, as it can be readily prepared from the natural zirconia by the method already briefly outlined. An iron-free oxide can also be prepared, according to a recent process, at a low cost.[3] The pure oxide mixed with sufficient sodium silicate or phosphoric acid to form a plastic mass, affords a cement or lute capable of withstanding the severe temperatures of electric furnaces of either the resistance or arc type.

*Refractory Properties of Natural Zirconia.*—To compete with the various high-grade refractory bodies now used industrially, zirconia must possess certain superior properties lacking in these cheaper refractories, such as a higher melting point or greater resistance to chemical agencies. In other words, the initial cost of a zirconia lining, which is rather high as compared with, for example, magnesite brick, is more than offset by its high melting point, (3200 deg. F. to 3600 deg. F.), high resistance to corrosive slags, metals or metallic oxides, low thermal conductivity and low coefficient of expansion. All of these superior factors indicate the life of a zirconia lining to be of very much greater duration than the best natural refractory lining now available.

Actual working tests made on a Martin-Siemens furnace in a steel works at Remscheider, Germany,[4] using a zirconia-lined hearth, show that after four months of continuous operation at high temperatures, the hearth was still in good condition and would serve at least four months longer before renewal. Careful statistics compiled from these tests show a saving of 50 per cent in actual maintenance costs in favor of the zirconia lining over an ordinary refractory lining such as is generally used. No allowance was made for increased production and higher efficiency. Owing to the low thermal conductivity of zirconia (about one-half that of ordinary fire brick), it has been demonstrated in actual practice that a 2-in. lining is equivalent to 4 in. of chamotte.

The high resistance of this refractory to such metals and alloys as copper, steel, bronze and red brass, should commend its use in their metallurgy. Gaseous or molten fluorides affect it markedly, however, likewise bisulphates, but as there are only a few substances inert to such corrosive compounds, this can be hardly cited as a detrimental feature.

As a protective coating or paint for ordinary fire brick exposed to the destructive action of acid fumes or slags, zirconia should find a limited application.

A suitable bonding medium for such a purpose might be found in a weak solution of water glass or sodium silicate.

All bonding material must be used advisedly, as they naturally tend to lower the fusing point of the refractory. In lining furnaces or other metallurgical apparatus, natural zirconia can be mixed with water-free tar as a binder, in which case wooden forms are generally used. These are allowed to remain in place and consumed during the initial heat. The temperature should be raised very slowly at first to eliminate the volatile products in the tar, after which a temperature of at least 1400 deg. C. must be maintained for about 48 hours. Natural zirconia begins to fuse at about 1800 deg. C., and at 2000 deg. C. there is a noticeable volatilization of silica and other impurities.

In the manufacture of natural zirconia brick, muffles, crucibles and small articles of refractory ware, about 2 per cent of air-slacked lime as a binder has been used with success. In practice, a batch composed of 75 per cent 100-mesh zirconia, 23 per cent of 10 mesh, and 2 per cent of slacked lime, is worked into a plastic with a 3 per cent solution of 38 deg. Bé. sodium silicate. The bricks or ware are then pressed from this and allowed to thoroughly dry in a warm atmosphere. The procedure from this point on is the same as in the burning of ordinary refractories, except that a temperature of at least 1400 deg. C. is necessary to secure the proper vitrification.

As the density of zirconia is rather high (about 4.2), it has been suggested where imperviousness is not desired, that the incorporation of certain organic substances or volatile salts which would be destroyed during firing, thus producing small air cells, might serve to lighten the finished product without impairing its efficiency. Sawdust, cork dust or certain ammonium salts might prove of value for such aeration.

---

[2] Ruff, Lieferfeld & Bruschke, Zeit. anorg. Chem., p. 389, 1911.
[3] German patent No. 262,009.
[4] Private communication.

The low coefficient of expansion renders zirconia ware free from all danger of fracture due to sudden changes of temperature. In this respect it resembles fused silica ware.

The cost of zirconia as compared to certain artificial refractories produced in the electric furnace is considerably lower, which, in view of its remarkable properties, should commend it strongly to the furnace man or metallurgist.

Foote Mineral Company,
Philadelphia, Pa.

## The Analoid Method for the Determination of Manganese in Steel, Iron Ore and Slag

The Scientific Materials Company, of Pittsburgh, Pa., through its research department, has recently taken up the problem of standardization of analytical methods for iron and steel laboratories. The first method undertaken was the determination of manganese.

The method selected as basis is the "Walters" or "persulphate" method, as it was considered preferable for routine analysis to any other, and as its general scheme is being practiced in a majority of iron and steel laboratories.

This method in brief consists of dissolving sample in nitric acid, adding measured amounts of silver nitrate and ammonium persulphate, holding the solution at about the boiling point until the oxidation of the manganese to permanganic acid is complete and finally cooling and titrating with a standard solution of sodium arsenite.

In the analoid method all the good points of the Walters method are retained, the operations standardized and at the same time simplified, by the application of the "analoids."

An "analoid" is a tablet containing just the exact quantities of the proper reagents, which have been carefully tested and apportioned to give the very best result for a certain reaction in the method for which it has been specially prepared.

### Method for Steel and Wrought Iron

Sample: 0.1 grm. for percentages of Mn from trace to 1.10 per cent.

Place in a 6-in. by 1-in. test tube. Measure on to sample, with dispensing burette, 10 cc of 1.10 sp. gr. nitric acid (one part $HNO_3$ of 1.42 sp. gr. to four parts water). Place in boiling water in carbon boiler. When the solution is complete, without removing from boiler, add one 8-A analoid (silver nitrate). This will dissolve immediately. Add one 8-B analoid (ammonium persulphate). One minute from the time the pink color first appears, remove the test tubes from the boiler and place in water bath to cool. When at room temperature, wash into a 4-in. porcelain dish with 15 cc to 20 cc of water and add 3 cc of sodium chloride solution (5 grams per liter). Titrate with N/100 sodium arsenite solution* until the pink color is just discharged.

The addition of the sodium chloride solution is recommended as stated above, since it materially sharpens the end point.

### Method for Cast Iron, Pig Iron and All Slags

(For percentages up to 4 per cent.)

Sample: 1 grm. if from trace to 2 per cent Mn, or ½ grm. if from 2 per cent to 4 per cent Mn.

Place in a 300-cc beaker. Dissolve in 40 cc $HNO_3$ sp. gr. 1.20 (one part $HNO_3$ 1.42 sp. gr. to one part $H_2O$). Simmer until all soluble matter is dissolved. Dilute filter and make up to 250 cc, mixing thoroughly. With pipette take 25 cc, and run into a 6-in. by 1-in. test tube and proceed as before but add two 8-A analoids (silver nitrate) and two 8-B analoids (ammonium persulphate).

Titration: Rinse into a small conical flask, dilute to about 60 cc. Run in 3 cc sodium chloride solution and titrate with N/100 sodium arsenite until pink color is discharged.

Slags containing sulphides should be boiled three or four minutes after solution is complete, to insure all sulphur being oxidized. In dissolving, to prevent clotting, add first a little water and when boiling, add acid slowly. If any tendency to clot appears throw out sample and start another with more water.

### Method for Ores

Sample: 1 grm. if from trace to 2 per cent Mn, or ½ grm. of from 2 per cent to 4 per cent Mn.

Place in a 4-in. evaporating dish. Dissolve in 20 cc of HCl sp. gr. 1.18. Simmer until soluble matter is dissolved. Add 2 cc to 3 cc of hydrofluoric acid. Simmer until silicates are decomposed.

Add carefully 15 cc concentrated $H_2SO_4$. Evaporate to fumes of sulphur trioxide. Cool, dilute to 40 cc with water, and boil until all the soluble matter is dissolved. Filter and make up to 250 cc. Proceed exactly as for cast iron, etc.

### The Analoids

The matter of preparing suitable analoids was a far more difficult chemical problem than might at first be supposed. It was finally solved in the laboratory of C. H. & N. D. Ridsdale, the distinguished English iron and steel chemists.

The purity of the chemicals which enter into the analoids is first tested and the method of preparation is the same as employed in the dispensing of poisons, where very minute quantities are equally apportioned in each tablet.

The binders used in preparing the analoids preserve the reagents employed, so that they keep almost indefinitely.

The "analoid" method first embodies all the advantages of the "Walters" or "persulphate" method, but the number of operations has been decreased and at the same time the precision with which each operation is performed has been greatly increased by using analoids.

In this method, the measuring out and adding to the determination of an amount of silver nitrate solution is entirely eliminated. This operation took some time and as practised in many laboratories was done inaccurately and delayed the operation because the aqueous solution of silver nitrate cooled the determination.

Furthermore, the operation of first making the silver nitrate solution is entirely eliminated, which had to be done quite frequently on account of the unstableness of the solution.

The possibility of error in results by using a silver nitrate solution which should have been discarded, is eliminated and, of course, the waste incurred by constantly disposing of the old solution is also done away with.

In the analoid method the addition of an 8-A (silver nitrate) analoid, which instantly dissolves, completes this operation.

---

* The N/100 sodium arsenite solution is made up of 0.491 gram of $AS_2O_3$ dissolved in 2 or 3 grams of sodium carbonate and hot distilled water, cooled and then made up to one liter with cold distilled water. Standardize against a steel of known manganese content. The sodium chloride solution is used in standardizing. For a 0.1 gram sample the N/100 sodium arsenite solution should equal about 0.11 per cent manganese per c.c.

In the old method the next operation is the addition of ammonium persulphate. This was done either by adding a solution or by adding the slightly moistened salt. The solution method requires weighing, and new solutions must be made frequently and the unused portion of the old solution discarded, as it quickly spoils. Often the solution is used when it should have been discarded and results are correspondingly incorrect. Time is lost owing to the necessity of measuring and adding the solution and the reaction postponed on account of the cooling effect on the determination.

The dry-salt method requires the weighing of each addition if the analyst is exact, but ordinarily the measuring is done by spoon, which, of course, is not exact. The operation is what is known in the laboratory as sloppy, because of the spilling and the sticking of the salt to the sides of the container in which the determination is being made. To correct this, the wash bottle is used, which takes time and changes the dilution of the sample.

When oxidation seems to be complete, the sample is removed from the source of heat. Some chemists perform the above-mentioned operation when sample is removed from source of heat and trust that the heat of the solution will be sufficient to complete the reaction. This, however, is not in accordance with the work of the more careful analysts who hold the determination at 100 deg. C. until oxidation is complete.

By the analoid method, one 8-B (ammonium persulphate) analoid is added, which acts immediately, and one minute later the test tube is removed from the water bath and cooled.

From this point the analoid method is the same as the Walters method and is finished by titrating the permanganic acid with standard sodium arsenite.

The time required for one determination by the analoid method is about nine to ten minutes including weighing, and for ten determinations about twenty minutes. For a great number, the time required may be figured at one minute per sample for the weighing and a further allowance of twenty-four to thirty minutes made for the manipulation, on a lot of fifty samples. With the exception of the weighing, the time required by the other method, as usually practiced, is at least twice as great.

In the analoid method every sample is treated exactly in the same way, whereas if the same precision were reached by the old method, the time required would be many times greater. In practice precision has usually been sacrificed for speed.

By diminishing the number of operations, as is done by the analoid method, the amount of apparatus required is also diminished, which permits the chemist to keep much neater and better appearing hoods and work benches.

This method is conductive to more accurate and careful work on the part of the operator because of its neatness and the fact that the necessity of hurrying is eliminated.

The Scientific Materials Company is extending the application of the analoid method to other routine analyses in iron and steel laboratories.

## A New High-Pressure Gas Valve

In valves for high-pressure gas cylinders the safety features are very important. The valve must be free from leaks and easy to operate and it should last a reasonable time. The International Oxygen Company, of Newark, N. J., as a large shipper of oxygen and hydrogen in cylinders, experienced in the early days considerable trouble with valves. They found, for example, that the average valve, even though made tight at the start, would not remain tight under high pressure. This occasioned losses from leakage sometimes as high as 25 per cent of the contents of the cylinder. Moreover, the packing in the valves was a source of trouble and if made of an inflammable material, such as leather, would even be a source of danger. The International Oxygen Company finally decided to take up a systematic research to develop a valve that would meet all requirements. As a result of a long series of experiments they evolved a high-pressure stud valve which is admitted to be unique, embodying principles of design and construction which are entirely original and eliminating the various objectionable features which caused their early troubles.

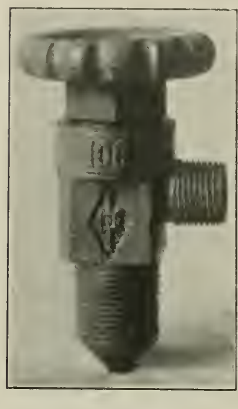

FIG. 1—HIGH-PRESSURE GAS VALVE

The I. O. C. stud valve can be used for pressures up to 2500 lb. It is specially recommended for oxygen, hydrogen, nitrogen and similar gases. It is made of noncorrosive metal throughout, no packing being used in any part. The body is forged tobin bronze, while the other parts are made of suitable metals which are noncorrosive to gases or to any weather conditions. Figs. 1 and 2 show the simple construction of the valve. Every part is accessible and if worn out can be easily replaced at little expense.

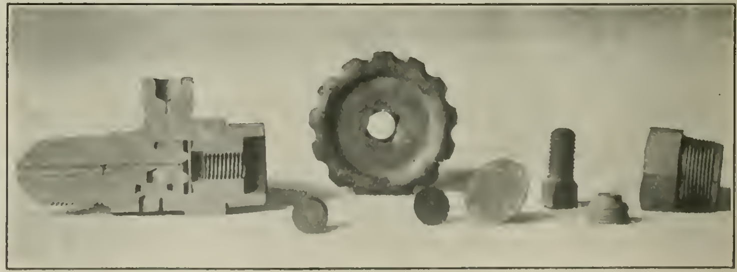

FIG. 2—SECTIONAL VIEW AND PARTS OF HIGH-PRESSURE GAS VALVE

The diaphragm is made of very tough and springy material that will withstand perfectly all the strain put upon it, without any possibility of its cracking or breaking even after many years of service. The diaphragm takes the place of packing material, and in this way the usual stuffing box is entirely eliminated. In the case of high-pressure oxygen gas, the studding box is extremely objectionable, as one must resort to the use of rubber, leather or similar inflammable materials.

The diaphragm is slightly concave, and is normally set away from the seat of the valve a sufficient distance to permit a full opening of the valve. It is not necessary, therefore, for the gas to raise the diaphragm; in this way all the gas from the cylinder can be used, down to atmospheric pressure.

An essential part of any high-pressure valve is its safety plug. In the I. O. C. valve this is an ingenious device which has received the approval of the Bureau of Explosives of the Interstate Commerce Commission. The plug is filled with fusible metal melting at, or below, the boiling point of water. It is provided with three passages, each in a straight line with the direct action of the gas in the cylinder to permit the outflow of the metal; is further provided with a hemispherical seat and a phosphor bronze disk. This safety plug is screwed into the body of the valve and forms a tight seat by compressing the phosphor bronze disk. No part of this plug projects beyond the body of the valve, this protecting it against breakage. The safety plug will not blow when submitted to the direct rays of the sun or any other atmospheric condition; but will blow when placed in a fire, before the expansion of the gas can do any damage to the cylinder.

This valve has been in use in the Newark works of the International Oxygen Company for a number of years and a great many valves are used by other gas manufacturers in this country and Canada. The valve has given entire satisfaction under all conditions of severe laboratory tests and of actual commercial service.

## A New Vacuum Pump for Vacuum Heating and Vacuum Filtration Systems

A novel vacuum pump has been put on the market by the Nash Engineering Company of South Norwalk, Conn., for use in connection with vacuum heating systems, vacuum filtration, or wherever air containing a large percentage of liquid has to be handled. The primary object of a vacuum pump in a heating system is to rapidly remove the air which is very detrimental to the efficiency of the system. The pump should do this without the necessity of introducing cooling water with consequent loss of heat. This is very effectively accomplished by the Nash hydroturbine.

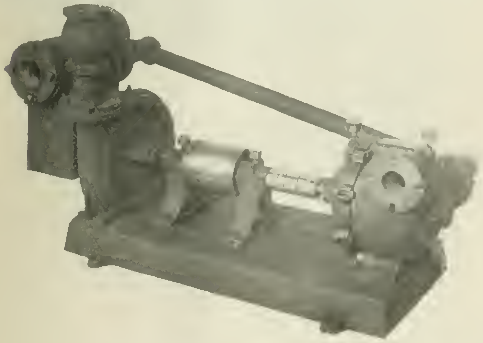

FIG. 1—HYDROTURBINE AND CENTRIFUGAL SET

Fig. 1 shows clearly the various parts. A Nash hydroturbine and Gould centrifugal are mounted in line on a cast-iron base. A separator is connected at the bottom to the centrifugal and near the top to the Nash pump. A check valve is placed on the outlet of the centrifugal.

The action of the outfit is as follows: As soon as the shaft is rotated the Nash hydroturbine produces a vacuum in the system, which draws water and air into the separator. The water falls to the bottom of the separator and is discharged by the centrifugal. The air is drawn from the top of the separator by the Nash pump.

As the amount of water handled varies, the centrifugal is made large enough to take care of the maximum quantity. When less water than this comes along the centrifugal continues to pump water until the separator is empty. The centrifugal then ceases to deliver water, but the check valve on the outlet prevents the vacuum from being broken.

As soon as the water has accumulated in the separator sufficiently to submerge the inlet, the centrifugal once more takes hold and pumps the water out.

The advantages of this simple combination are at once apparent. The water and air are handled separately in pumps specially designed for the purpose, the air in an air pump, the water in a water pump, which means greatly increased efficiency. The water may be delivered efficiently against a head without putting any back pressure against the air pump, which means a big saving in power as the air pump is of relatively large volume as compared with the water pump. It is possible to handle water containing dirt and abrasive material, as this all passes through the centrifugal, which is adapted for this service, and furthermore may be replaced at small expense if it finally is worn out.

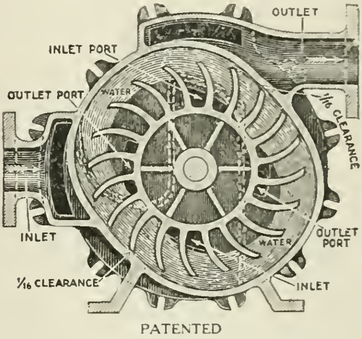

FIG. 2—CONSTRUCTION OF PUMP

An examination of Fig. 2, illustrating the interior of the Nash pump, shows the simple and efficient principle upon which it works and why it is specially adapted to the service described above.

The water follows the case, due to centrifugal force. Twice in a revolution the water recedes from the rotor, thereby leaving spaces between the blades into which air is drawn through the inlet ports. The water then surges back into the rotor, compressing and delivering the air through the outlet ports. The water seal prevents leakage. The water is used continuously. The suction is uniform. The pressures on the shaft due to compression are balanced. There are no valves or loose moving parts. The rotor is the only moving element and is fitted with ample clearance.

The large volume of air handled by the Nash pump keeps the centrifugal primed and free from air, which means that it works at its highest efficiency. The large volumetric capacity also makes it possible to produce a vaccum when handling extremely hot water. Under this condition the action of the pump is as follows:

The vacuum rises until the point is reached where the water becomes steam at the existing temperature. The Nash pump takes the steam away as fast as formed. The steam is drawn into the pump under a vacuum and is compressed by the pump and delivered at atmospheric pressure.

As the steam is compressed some of it condenses and is delivered as water.

The reliability of this outfit is one of its strongest points, as both pumps have only one moving part, running with a clearance. There are no valves or piston packing to require attention.

The machine shown in Fig. 1 is arranged for belt drive. It can also be built for direct connection.

## A New Water Still

The following article describes a new water still involving several interesting novel features. It is built by the A. P. Link Manufacturing Company, 212 Thirty-ninth Street, Brooklyn, N. Y.

The still is shown diagrammatically in Fig. 1, with the boiler at the left and the condenser at the right. An outside view of the still is shown in Fig. 2.

The apparatus is made entirely of copper, heavily tinned with pure block-tin, and has an easily removable sediment receiver which can be conveniently placed inside of the boiler where it keeps the water in constant circulation from the outside towards and up through the center, depositing all the sediment in a sediment cup, thereby preventing the settling of any sediment and any encrustation along the boiler surfaces. By these means also a larger steaming surface is obtained than can be produced with a flat boiling surface only.

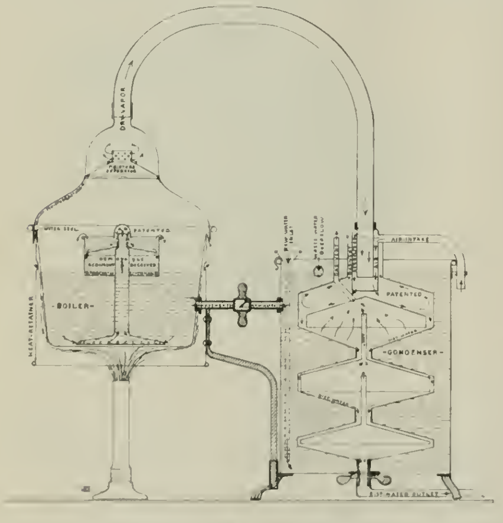

FIG. 1—DIAGRAM OF WATER STILL

The water in the boiler is constantly kept at its proper level by means of a very simple hinge check valve, which permits the water to flow from the condenser to the boiler (from right to left in the diagram) but not in the opposite direction, so that it is impossible for undistilled water to pass over to the condenser.

The water before entering the boiler is pre-heated by the steam from the boiler and can be kept at any desired temperature so as to free the water from a great amount of ammonia and other gases before it is admitted to the boiler.

Another novel feature in the boiler is the provision which has been made to separate moisture (which is more or less contaminated) from the splashing bubbles which are projected against the inner surfaces of the cover or other parts of the boiler so that this moisture cannot be entrailed into the condenser whereby naturally the distilled water would be rendered impure to a certain extent. This feature has also been well tested out and found very successful in eliminating all moisture from the vapors before they leave the boiler cover. Such moisture is returned to the boiler immediately by its own gravity, and without loss of heat units.

The vapors arriving at the condenser neck can be permitted to syphon an abundant amount of free air which is sterilized around the steam pipe proper, within the condenser neck. The air is finally mixed with the steam and water while projected against the walls of the condenser, which are surrounded by water. The water vapors are immediately condensed while the remaining gases are liberated according to their specific gravity in a discriminating manner at various points, which is accomplished without loss of water vapor. This air syphon is made use of when well aerated water is desired for drinking purposes. If non-aerated water is desired, all that is necessary is to stop up the air intake, whereas the elimination of all the gases is never interfered with.

The second venting tube is at the same time an indicator for the operator if the water in the condenser should become too hot. In this case this vent tube shows a slight escape of steam, so that by this means the proper temperature of the condensing water can be easily obtained, or the apparatus so operated as to eliminate any and all gases according to the temperature at which the condensing water is being kept.

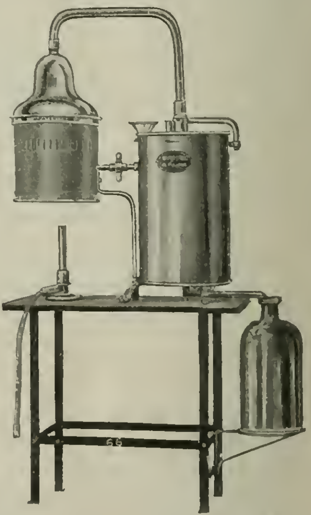

FIG. 2—OUTSIDE VIEW OF WATER STILL

It is obvious that with this apparatus, even very polluted water can be distilled to absolute purity. The distilled water leaving the condenser at the bottom is cool, practically at the same temperature as the raw water fed through the inlet.

The raw water from the inlet is always projected against the lowest part of the condenser, whereby the temperature of the water on top of condenser can be constantly kept at the desired degrees to accomplish the desired results.

All parts of the still are easily accessible, can be readily taken apart and cleaned and re-assembled without delay, and without use of any tools or experience. The whole apparatus consists of *only five parts*, boiler, condenser, sediment receiver, cover, and vapor pipe. It is portable and can be readily set up and operated upon any shelf, a table, a stand, a stove, or wherever convenient or it can be set up permanently and connected with any gas, water and steam supply.

# A New Electrical Long-Distance Transmitting Indicating and Recording System

A new electrical long-distance transmitting indicating and recording system is being placed on the market by The Bristol Company, Waterbury, Conn. In these instruments Bards patent long-distance induction-balance movements are employed as especially developed for this purpose by the Sangamo Electric Company. Bristol recording instruments, when equipped with these electrical transmitting systems, are capable of producing automatic and continuous records of pressure, liquid levels, temperatures, mechanical motions, etc., at long distances, even many miles from points at which the transmitters are located.

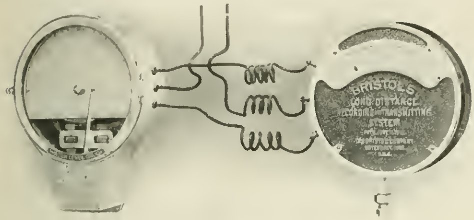

FIG. 1—STANDARD UNIT OF TRANSMITTING AND RECORDING INSTRUMENT

Fig. 1 shows a standard unit of these transmitting and recording instruments, including the transmitting indicator for installation at the point where the pressure or temperature, etc., is measured, and the receiving recorder which is installed at the remote point where it is desired to have the printed record produced.

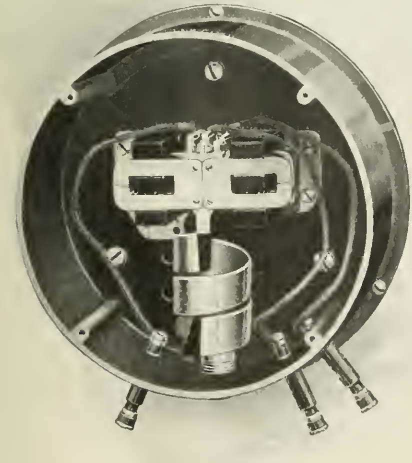

FIG. 2—INTERIOR OF TRANSMITTING INSTRUMENT

The two instruments are shown connected by three wires, one of which is connected in the manner indicated to a source of alternating current, as for instance, a lighting circuit.

This long-distance system is particularly well adapted for use under ordinary operating conditions because of its simplicity of construction. There are no sliding or make-and-break contacts employed, and the effects of variation of temperature or resistance along the circuit are negligible. The recording instrument may be installed many miles distant from the measuring and transmitting device. For instance, if 110 volts and No. 14 copper wires are used, the recorder may be located thirty miles from the transmitter, or if No. 12 leads are used the recorder can be installed forty miles or more from the transmitter. The transmitting device is mounted in moisture-proof case, and can be installed outdoors if necessary, as, for instance, on the bank of a reservoir.

FIG. 4—TOP OUTLINE DIAGRAM OF TRANSMITTING DEVICE

The fundamental principle of the Bristol long-distance transmitting and recording system is that of the induction balance. The transmitting instrument and the receiving instrument are each equipped with two pairs of coils arranged to swing in a horizontal plane over iron cores. Fig. 2 shows the interior of one of the transmitting instruments. In this instrument the helical form pressure tube and the electrical transmitting device are shown in the operating position.

Figs. 3 and 4 are detailed front and top outline diagrams of the transmitting device, which is similar to the receiving device.

The complete outfit consists of two pairs of mechanically balanced solenoids arranged to swing horizontally back and forth over the ends of soft iron cores and connected in parallel to an alternating-current circuit. One pair of the solenoids is used for the transmitting instrument, the other pair for the receiving instrument. Front view, Fig. 3, of the transmitter shows one pair of the solenoids A and B on spools connected together and supported on a shaft, the ends of which rest in jewel bearings at G and F and free to swing back and forth over laminated soft iron cores C and D. The top view, Fig. 4, shows the solenoids A and B of the transmitter in section and by the dotted outline the position to which the solenoids may swing is also indicated.

A similar pair of balanced solenoids is placed in the receiving recorder or indicator at the distant point. When the solenoids A and B of the transmitter and receiver are connected in parallel to an alternating-current circuit and the transmitter coils A and B are held in some certain position by the operating mechanism located at E (water level gauge, pressure gauge, thermometer, etc.), the relative amounts of current flowing in solenoids A and B will depend on their positions on the iron cores C and D due to the inductive effect of same.

At the receiving instrument the other pair of solenoids are mechanically balanced and free to take an angular position which will be the same as that of the transmitter since the flow of current will be the same in the corresponding solenoids of the receiver as in the transmitter. If the angular position of the pair of solenoids at the transmitter is changed by the operating mechanism thus moving one of the solenoids off and the other on to the iron cores, increasing the inductance in one solenoid and diminishing it in the other, the flow of current will be proportionately increased in one coil and diminished in the other. The variations of current at the distant receiver will correspond with the variations at the transmitter, and cause the pair of solenoids of the receiver to seek a position of balance which will be the same as that of the solenoids of the transmitter.

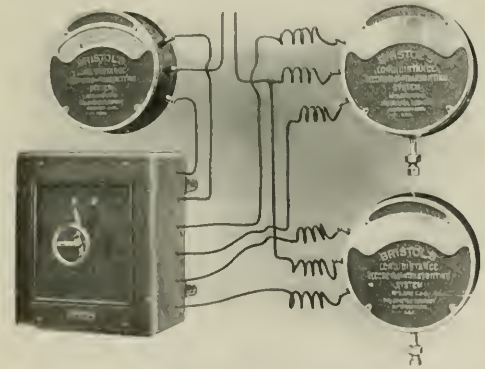

FIG. 5—COMBINATION OUTFIT OF TWO TRANSMITTERS AND ONE RECEIVING INDICATOR

In the transmitter the operating mechanism is linked directly to the balanced solenoids by means of an arm L. In the receiver the recording pen or the indicating pointer is connected to a similar arm through a simple and practically frictionless multiplying mechanism.

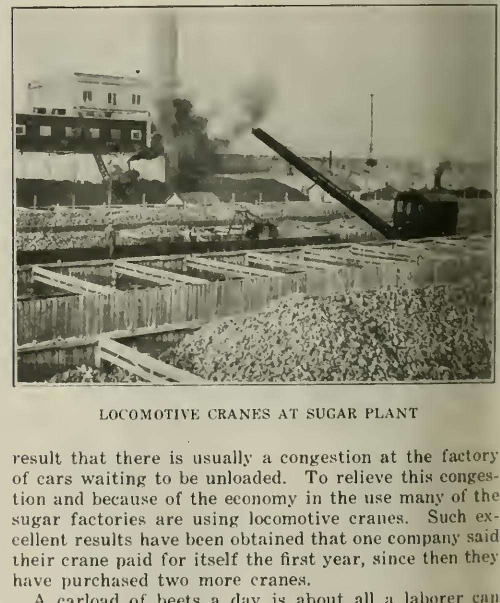
Various combinations of transmitting and receiving instruments of either indicating or continuous recording type may be furnished. Fig. 1 illustrates the standard equipment including a transmitting indicator and a receiving recorder, but it is possible to furnish the transmitter and receiver in either the indicating or recording type. Fig. 5 shows a combination outfit including two transmitters and one receiving indicator connected with a two-point rotary switch so that readings may be obtained with the indicator of the pressures, temperatures, etc., from either of the transmitters.

A great variety of applications for this apparatus will arise owing to its flexibility and extreme simplicity.

## Locomotive Cranes

The accompanying illustration shows in an interesting manner the efficient handling of bulk materials at a beet sugar factory by means of locomotive cranes. One of the cranes is being used to place coal in bunkers above the power house, while the other is unloading sugar beets from cars into the beet bin.

The beet harvest usually does not begin until about the middle of October and then the farmers try to deliver their beets before cold weather sets in, with the result that there is usually a congestion at the factory of cars waiting to be unloaded. To relieve this congestion and because of the economy in the use many of the sugar factories are using locomotive cranes. Such excellent results have been obtained that one company said their crane paid for itself the first year, since then they have purchased two more cranes.



LOCOMOTIVE CRANES AT SUGAR PLANT

A carload of beets a day is about all a laborer can unload by hand, while three men and a crane will unload from three to four cars an hour. In addition to the saving effected the crane does its own switching of cars so that rapid unloading is greatly facilitated. The crane in the foreground is using the special beet fork built so as not to crush the beets when handling them. Beneath the beet bins there are sluices to allow the beets to be transported to the factory by a rapid current of water.

Just before the picture was taken the farther crane loaded two 40-ton cars with coal from a reserve pile in twenty-five minutes. It then brought one of them around to the power house and placed the coal in elevated bunkers as shown. It also handles beets and limestone and is otherwise generally useful around the factory. The picture was taken at the plant of the German American Sugar Co. at Bay City, Mich., the locomotive cranes being made by the Industrial Works of the same city.

## Automatic Sampling of Mill Pulps

The automatic sampler described in this article is the design of Mr. Elmore and is being built by Messrs. F. W. Brackett & Co., Ltd., Colchester, England. The construction of the Elmore sampler is shown in the adjoining illustration.

It is to be noted that the sampler can be set with driving shaft at any angle in relation to the launder conveying the pulp to be sampled. By simply sliding the adjustable arm on the center pin, the machine is at once adapted to various widths of launders.

The sampler is put into operation by motion imparted through a round belt on the grooved pulley *Q* which is keyed to the shaft *P;* this in turn rotates the worm engaged with the worm pinion. This worm pinion operates an eccentric (not visible on the illustration) which reciprocates the pawl *R* causing the main ratchet wheel *O* to advance one tooth at a time. Thus the main ratchet wheel *O* is caused to rotate slowly.

To the upper face of *O* a toothed segment *N* equal to about one-sixth of the periphery of *O* is securely attached, the teeth of which are of the same pitch as those of the worm pinion. By the slow rotation of the main ratchet wheel *O* the segment *N* gradually approaches the worm pinion and engages with it, which immediately results in the quick movement of *N* and *O;* and as these carry the pin *E* to which is attached the sampling cup and discharge pipe *H*, it follows that during about five-sixths of each revolution (the non-sampling period) the main ratchet wheel *O* is moving at a very slow rate, whereas, for the other one-sixth of the revolution (the sampling period) the rate of movement is high, and the sampling cup thus cuts through the whole stream of pulp at a perfectly uniform rate of speed, and always at the same relative angle, during the whole period of sampling.

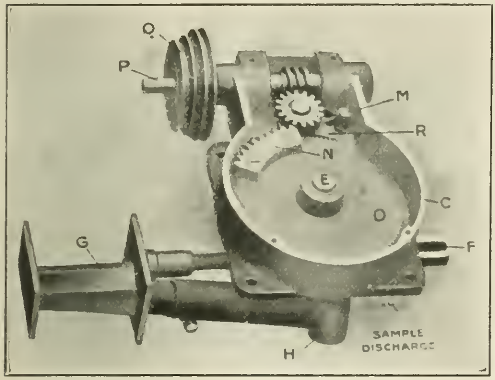


FIG. 1—AUTOMATIC SAMPLER

All the bearings and moving parts are enclosed in a substantial outer casing *C* covered with a dust-tight lid thus forming an oil bath, and providing perfect lubrication, minimizing wear and tear, and insuring continuity of working.

## Personal

Messrs. **Ernest Bamberger, Duncan MacVichie** and **H. L. Lambrecht** have been appointed by the United States District Court as appraisers of the tangible assets of the Ohio Copper Co.

Mr. **H. J. Baron**, manager of the Mexican Chemical Co., Chihuahua, Mexico, spent ten days in Denver last month in the course of a business trip to the States.

Mr. **Fred W. Bradley**, president of the Bunker Hill & Sullivan Mining Co., was tendered a reception recently at Kellogg, Idaho, at which he spoke enthusiastically regarding the development of the dry chlorination experiments that have been under way for some months past.

Mr. **T. H. Davis** has resigned his position as vice-president and general manager of the Rahway Chemical Co., of Elizabeth, N. J., and will manage the new plant of the Rahway Coal Tar Products Co., which will be in operation at Rahway, N. J., early next year. The new company is controlled by Merck & Co., of New York.

Mr. **Philip DeWolf**, chemical engineer, of Bristol, R. I., left for Memphis, Tenn., to investigate the possible local production of potassium salts, the supply of which to this country from abroad has been seriously curtailed since the beginning of the European war.

Mr. **J. C. Farrant**, European representative of the Hardinge Conical Mill Co., is a British prisoner at the Doeberritz detention camp near Berlin.

Mr. **H. C. Hoover**, who has been so prominent in the relief work in Europe since the opening of the war, is engaged in administrating relief measures in Belgium.

Mr. **A. J. Hoskin**, of Denver, has been in the gold mining districts of Georgia on professional business.

Mr. **John L. Malm** has returned to Denver from Kellogg, Idaho, where he is engaged in consulting metallurgical work for the Bunker Hill & Sullivan Mining Co. He expects to resume his duties at Kellogg after a brief absence on other professional duties.

Mr. **A. M. Plumb**, of the technical staff of the American Zinc Ore Separating Co., has been transferred from Denver to Platteville, Wis., where he will be engaged in a consulting capacity on the separation of zinc ore at the mill of the Wisconsin Zinc Co.

Prof. **Robert H. Richards** will be tendered a complimentary dinner at the Copley-Plaza Hotel, Boston, on Monday evening, December 7, "in recognition of his fifty years as a devoted Tech man and in expression of the respect and affection in which he is held by the Corporation, Faculty and Alumni of the Massachusetts Institute of Technology."

Mr. **James E. Russell** has been appointed assayer in charge of the United States assay office at Deadwood, S. D.

Mr. **Peter J. Weber**, city chemist of the city of Milwaukee, has resigned to accept the management of the American Metal Products Company of Milwaukee.

Mr. **Robert E. Wilbur** has been appointed assistant to the general manager of the Bethlehem Foundry & Machine Company.

## Digest of Electrochemical U. S. Patents

Prior to 1903.

*Arranged according to subject-matter and in chronological order.*

*Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.*

*Electroplating* (Continued)

626,330, June 6, 1899, Carl Luckow, of Cologne-Deutz, Germany.

Relates to making peroxide of lead, and consists in electrolyzing a solution containing, say, $1\frac{1}{2}$ per cent of a mixture of ninety-nine and one-half parts by weight of sulfate of sodium and five-tenths part by weight of chlorate of sodium, using electrodes of lead. The current density should be $\frac{1}{2}$ amp per sq. decimeter at about 3 volts. To facilitate the reaction and to keep the electrolyte in motion, air is carefully blown in during the process.

629,070, July 18, 1899, Pompeo Garuti and Riccardo Pompili, of Naples, Italy.

Relates to generating oxygen and hydrogen by the electrolysis of alkaline hydroxide solutions, and refers to his prior patent No. 534,259, on which the present patent is an improvement. The improvement consists in perforating the lower part of the insulated metal diaphragm with many small holes, or not more than 1 mm diameter, which prevents any gas escaping from one side to the other, and reduces the electrical resistance of the cell. The electrodes do not extend below the upper row of holes in the diaphragm.

630,246, Aug. 1, 1899, Frank S. Loeb, of New Kensington, Pa.

Relates to preparing aluminium for electrodeposition. The aluminium is first cleaned of any dirt, grease, etc., and rinsed in hot water. It is then immersed in dilute hydrofluoric acid, containing 25 cu. cm to 2 liters of water, until hydrogen gas is freely evolved; it is then removed and at once immersed in a "quicking" solution composed of 50 gr. of mercury dissolved in 100 cu. cm of strong nitric acid, this being added to 2 liters of water, and 30 gr. of potassium cyanide added; about five seconds immersion is sufficient; it is then reimmersed in the hydrofluoric acid until hydrogen is evolved, and then transferred to an electroplating bath. For copper plating, the following electrolyte is used: 8 oz. of copper acetate is made into a thick paste with water, then add 8 oz. of sodium carbonate dissolved in 2 qt. of water. In a separate vessel, dissolve 8 oz. of sodium bisulfide in 2 qt. of water, and add this to the copper acetate solution; then dissolve 6 oz. of potassium cyanide in 3 qt. of water, and add to the previous mixture, then add 5 qt. of water, bringing the volume to 3 gal. The bath should be used hot, about 130 deg. to 180 deg. F. Directions are also given for making electrolytes for depositing brass and silver.

647,858, April 17, 1900, Eduard Mies, of Büdesheim, Germany.

Relates to preparing aluminium to receive electrolytic deposits of other metals. The aluminium is heated for about five minutes in a boiling solution of phosphate of sodium and sulphate of magnesium, slightly acidulated with sulfuric acid, and then washed and then immersed in the ordinary electrodepositing baths as cathode and electroplated. The solution containing the phosfate of sodium, etc., probably corrodes or etches the surface of the aluminium, enabling the electrodeposited metal to adhere firmly.

653,715, July 17, 1900, Jean Theodore Van Gestel, of New York, N. Y.

Relates to an apparatus for producing a water-repellent surface on cloth or similar fabric, by immersing the cloth in a tank of water through which an electric current is passing, and then passing the wet cloth between one or two pairs of traveling metallic belts, the first pair so connected electrically that a current passes through the cloth in one direction, thereby producing a water-repellent surface on one side, and the second pair so connected electrically that the current passes through the cloth in the opposite direction, thereby producing a water-repellent surface on the other side. The traveling belts consist of upper and lower horizontal belts, each made of pieces of metal united with hinge joints, zinc being used as the anode, and copper for the cathode. The belts of each pair are supported on polygonal rolls driven by link chains and gearing, electrical contact being made with the belts by rollers for the upper belt and supporting pressure surfaces for the upper side of the lower belt. The lower side of each lower belt travels through a tank containing water which serves to wash off any impurities that may have collected thereon. The belts may be covered with a layer of cotton cloth to prevent short-circuiting. A pair of rubber rolls remove any surplus water from the cloth after treatment. (See patent 653,716.)

653,716, July 17, 1900, Jean Theodore Van Gestel, of New York, N. Y.

Relates to rendering cloth and similar fabrics waterproof and to setting the dye therein. The cloth is immersed in a solution of a metallic salt or salts and then subjected to the action of the electric current which causes an oxid of the metal to be formed in the interstices of the fabric. In fixing a dye the metallic salts are applied to the fabric either with the dye, or to the already dyed fabric as above described. For white goods a soluble salt of any suitable metal that will produce a white oxid, such as aluminum, is used, while for dark goods a soluble salt of a metal that will produce a dark oxid, such as iron, is used; and for goods of other colors, the soluble salt of a suitable metal such as will not change the color, may be chosen in accordance with well-known coloring properties of metals. The apparatus used is substantially the same as in patent No. 653,715.

## Book Reviews

**The Cleaning of Blast-Furnace Gases. By Frederick H. Wagner.** 168 pages, 58 illus. Price, $2. New York: McGraw-Hill Book Company, Inc.

A very timely work, in view of the fact that the subject is continually claiming increased attention. The chapters deal with the theory of condensation and cooling, dry dust catchers, wet cleaning, final cleaning, operative plants in America, and the storage of gas. These are all admirably handled except the theory of cooling and condensation, which contains too much of the academic theories of Dr. W. Feld. The four deductions on page 14 regarding infinite volume and infinite heat capacity of certain mixtures of gas and water vapor are neither pertinent, useful, nor instructive. The other chapters are all commendably good.

**Fuel: Solid, Liquid, and Gaseous. By J. S. S. Brame.** Octavo (14 x 22 cm.), 372 pages, 70 illustrations; price $3.50 net. New York: Longmans, Green & Co. London: Edward Arnold.

The author is lecturer on fuel at the Royal Naval College, Greenwich, and this volume is intended primarily to consider fuels in their relation to power, but their application to other purposes has not been omitted. It is intended primarily for engineers and technical men to whom the production of power is of importance.

It is a very satisfactory and useful book. The author discusses the composition, properties and calorific values of the different fuels in a masterly manner, which is commendably scientific as well as highly practical.

The only serious slip found was that the author seems unaware that the specific heats of gases at high temperatures are now known with fair accuracy, rendering possible satisfactory calculations of maximum flame temperatures. Using the old specific heats, which lead to impossibly high temperatures, he properly brands the results as absurd, and then dismisses the whole subject. The book would be improved by a short chapter on this topic.

The burning of coal dust is not given as much prominence as its successful applications in America to cement and metallurgical furnaces would warrant.

Aside from these two items the work is very well written, and as a whole it is strongly recommended to all interested in fuels and their investigation.
